ABSTRACT

In this third paper in a series of three, we present a detailed study of the broadband spectral energy distribution (SED) of active galactic nuclei (AGN) based on a nearby unobscured Type 1 AGN sample. We perform a systematic cross-correlation study of several key parameters, i.e. $\Gamma_{2-10\text{keV}}$, $L_{2-10\text{keV}}$, $L_{\text{bol}}/L_{\text{Edd}} = \lambda_{\text{Edd}}$, $L_{\text{bol}}/L_{2-10\text{keV}} = \kappa_{2-10\text{keV}}$, $L_{\text{bol}}/L_{5100\text{\AA}} = \kappa_{5100\text{\AA}}$, $\text{FWHM}_{H\beta}$, M_{BH} , α_{ox} , α_X and α_{UV} . The well defined spectral properties of the sample enable us to improve existing relations and to identify new correlations among these parameters. We confirm a break region around $\text{FWHM}_{H\beta} \simeq 4000 \text{ km s}^{-1}$ in the $\Gamma_{2-10\text{keV}}$ vs. $\text{FWHM}_{H\beta}$ correlation and $\text{Log}(M_{\text{BH}}) \simeq 8.0$ in the $\Gamma_{2-10\text{keV}}$ vs. M_{BH} correlation, where these correlations appear to change form. Beyond the break point the intrinsic $\Gamma_{2-10\text{keV}}$ index is dispersed around 1.8. Several new correlations are also reported in this paper e.g. strong correlations in κ_{5100} vs. λ_{Edd} , κ_{5100} vs. $\kappa_{2-10\text{keV}}$ and $\kappa_{2-10\text{keV}}$ vs. M_{BH} . The principal component analysis (PCA) is performed on the correlation matrix of the above parameters. This shows that the three physical parameters, i.e. black hole mass, mass accretion rate and Eddington ratio, drive the majority of the correlations. This is consistent with PCA results found from previous optical spectral studies.

For each key parameter, we split the AGN into three sub-samples, binned based on increasing value of that parameter. We co-add the model SEDs for each object in the sub-sample to see how the SED changes with that parameter. Most parameters, except L_{bol} , show similar systematic changes in the SED such that the temperature at which the disc peaks is correlated with the ratio of power in the disc versus the Comptonised components and the hard X-ray spectral index. This underlying change in SED shape shows that AGN do exhibit intrinsically different spectral states. This is superficially similar to the SED differences in BHB (black hole binary) seen as λ_{Edd} increases, but the analogy does not hold in detail. Only objects with the highest λ_{Edd} appear to correspond to a BHB spectral state (the disc dominated high/soft state). The AGN with typical mass accretion rates have spectra which do not match well with any state observed in BHB. We speculate that this could be due to the presence of a powerful UV line driven disc wind, which complicates simple mass scaling between stellar and supermassive black holes.

Key words: accretion, broadband SED modeling, active-galaxies: nuclei

1 INTRODUCTION

The broadband spectral energy distribution (SED) of active galactic nuclei (AGN) has been studied for many years. The unobservable gap between the extreme UV and soft X-rays, imposed by Galactic photoelectric absorption sets a major barrier to reconstructing the overall SED. This is particularly problematic because it is in this energy range that the peak of the SED often occurs. Due to this diffi-

culty, most previous work focused on spectral properties of either the optical/UV side (e.g. Sanders et al. 1989; Francis et al. 1991; Zheng et al. 1997; Vanden Berk et al. 2001), or the X-ray side (e.g. Wilkes & Elvis 1987; Green et al. 1995; George et al. 2000). However, the multi-wavelength combination is required to see the overall SED behaviour (e.g. Elvis et al. 1994; Laor et al. 1997; Richards et al. 2006; Shang et al. 2005; Lusso et al. 2010, hereafter: Lusso10). In order to recover the spectral shape in the UV/soft X-ray gap, some studies simply connected the optical/UV and X-ray spectra to estimate the SED (e.g. Elvis et al. 1994;

^{*} E-mail: chichuan.jin@durham.ac.uk

Richards et al. 2006; Shang et al. 2005; Lusso10). As the origin of the optical and hard X-ray emission became clearer, more broadband SED models with multiple physical components were used to fit the multi-waveband spectra. These were used to extrapolate across the UV gap based on the model assumptions, but with better justification than before (e.g. Middleton, Done & Gierliński 2007; Vasudevan & Fabian 2007, hereafter: VF07; Vasudevan & Fabian 2009, hereafter: VF09; Jin et al. 2009; Grupe et al. 2010, hereafter: Grupe10). For example, VF07 used a power law plus accretion disc model to construct the broadband SED for their sample. This technique was repeated in VF09 based on 29 AGNs from the reverberation mapping sample (Peterson et al. 2004), and using simultaneous optical/UV and X-ray data from XMM-Newton. Grupe10 used an absorbed power law for the X-ray spectrum, and an exponentially cut-off power law (or a broken power law) for the optical/UV spectrum, to construct the broadband SED for their sample, for which simultaneous optical, UV, X-ray data are available from SWIFT. Further discussion of some previous SED studies is given in Jin et al. (2011) (hereafter: Paper-I).

Within these works, some specific AGN parameters were studied, including black hole mass (M_{BH}), Eddington ratio ($L/L_{Edd} = \lambda_{Edd}$), bolometric luminosity (L_{bol}), 2-10 keV luminosity ($L_{2-10keV}$), 2-10 keV photon index ($\Gamma_{2-10keV}$), $H\beta$ FWHM. Also, some parameters directly related to the broadband SED shape were proposed, such as the optical to X-ray spectral index (α_{ox} ¹, Tananbaum et al. 1979), 2-10 keV bolometric correction ($\kappa_{2-10keV}$, defined as $L_{bol}/L_{2-10keV}$, e.g. VF07), 5100Å luminosity scaling factor (κ_{5100} , defined as L_{bol}/L_{5100} , where L_{5100} is the monochromatic luminosity at 5100Å, Kaspi et al. 2000).

Since the number of AGN with both high quality optical/UV and X-ray spectra is relatively small, much effort is devoted to search for correlations among the key SED parameters, especially those parameters capable of representing the broadband SED shape. Then, for those many AGNs lacking sufficient spectral information, these correlations can be used to predict the SEDs that cannot be defined from direct observation. Indeed, many such parameter correlations have been proposed. For example, VF07 reported a strong correlation between $\kappa_{2-10keV}$ and λ_{Edd} (VF07; VF09; Lusso10). Correlations were also found between $H\beta$ FWHM and $\Gamma_{2-10keV}$ (e.g. Leighly 1999; Reeves & Turner 2000; Shemmer et al. 2006, hereafter: S06; Shemmer et al. 2008, hereafter: S08; Zhou & Zhang 2010, hereafter: Zhou10a), between λ_{Edd} and $\Gamma_{2-10keV}$ (e.g. Lu & Yu 1999; Porquet et al. 2004; Wang, Watarai & Mineshige 2004; Bian 2005; S06,08), and between $H\beta$ FWHM and λ_{Edd} (e.g. Grupe10; Paper-I). The correlation between L_{2500} and L_{2keV} is another important result, which led to further correlation studies related to α_{ox} , L_{2500} , L_{2keV} and redshift (e.g. Green et al. 2009, see references given in Table 2.2). In table A1, we list some of the principal parameters, and list the relevant papers discussing the correlations. Later in the papers we will discuss some additional correlations e.g. M_{BH} vs. $\Gamma_{2-10keV}$ and M_{BH} vs. $\kappa_{2-10keV}$, in the context that changes in these parameters are caused by changes in the fundamental physical processes.

However, due to the difficulty in obtaining and analyzing both optical/UV and X-ray spectra for a large sample, these parameter correlations are reported separately and based on different samples, rather than being studied systematically for a single well-defined sample. Furthermore, most of the previous samples were not selected based on their spectral properties, so effects such as reddening will introduce biases into the cross-correlations. The lack of a self-consistent physically motivated broadband model, has also been a constraint to performing a more detailed SED study.

In Paper-I, we defined a sample of 51 Type 1 AGNs with both optical/UV and X-ray spectra which are of high quality, and without evidence of complex spectral absorption features e.g. a warm absorber. Based on this bright and unobscured Type 1 AGN sample, we applied our latest optical and broadband SED model to perform the spectral fitting, and so matched the optical spectrum and produced a broadband SED for each AGN in the sample. This is so far the most detailed spectral analysis for a medium sized sample of AGNs, with such well defined high quality spectra. In our preceding paper (Jin, Ward & Done 2012, hereafter: Paper-II), we studied the Balmer emission line properties and the Relation between the optical and X-ray emission, based on the same sample and the spectral fitting results given in Paper-I. This paper is based on the sample of Paper-I, but focuses on the shape of the broadband SED, and how this relates to a range of parameters from the model. We will approach this problem by first investigating the numerous correlations previously reported. Then a set of mean SEDs based on key parameters are constructed and studied in detail.

These mean SEDs show a clear change in shape as a function of the AGN parameters, probably most fundamentally driven by a change in λ_{Edd} . The SED becomes more disc dominated and the X-ray tail softens as λ_{Edd} increases (e.g. Grupe et al. 2010). This is superficially similar to the changes seen in the Galactic black hole binary (BHB) systems as the mass accretion rate increases. In BHB at low Eddington ratio ($\lambda_{Edd} \leq 0.02$) the X-ray spectra are hard, $\Gamma_{2-10keV} < 2$, and the disc emission is weak (low/hard state). As the mass accretion rate increases the disc increases in importance relative to the tail, and the tail steepens until it reaches the disc dominated ‘thermal state’ (also known as the high/soft state) where the power law tail is somewhat steeper $\Gamma_{2-10keV} \sim 2 - 2.2$. At high Eddington fractions the source can also show a ‘very high’ or steep power law state, where both disc and tail contribute to the spectra, but the spectra are typically steep ($\Gamma_{2-10keV} \geq 2.2$) (Remillard & McClintock 2006; Meyer-Hofmeister, Liu & Meyer 2009). It has been proposed that AGNs are simply scaled up counterparts to the BHBs, so they should also show similar spectral states (Done & Gierliński 2005; McHardy et al. 2006; Gierliński et al. 2008; Middleton et al. 2009; Jin et al. 2009). Therefore the Eddington ratio may also be a good indicator an AGN’s accretion state, and so determine the shape of its SED, explaining the multiple strong correlations between various SED parameters.

This paper is organized as follows. Section 2 gives a brief description of the main characteristics of the sample, and the method used for fitting the broadband SED. Further details of this are presented in Paper-I. In Section 3

¹ $\alpha_{ox} = -\frac{\log(F(2keV)/F(2500\text{\AA}))}{2.605}$, assuming $F(\nu) \propto \nu^{-\alpha}$ to ensure a non-negative α_{ox} .

we examine the parameter correlations across five parameter groups. Some significant new correlations are proposed. In Section 4 we perform a systematic study of all correlations among several selected key parameters, and build a cross-correlation matrix. The principal component analysis technique is used on this correlation matrix in order to derive the eigenvectors. In Section 5 various mean SEDs are constructed, based on the mean values of the key parameters. In Section 6 we investigate further the reliability of these correlations, including the effect of a correction to the black hole mass from radiation pressure. In Section 7 we summarize our results, and propose topics for further study. A flat universe model with a Hubble constant of $H_0 = 72\ km\ s^{-1}\ Mpc^{-1}$, $\Omega_M = 0.27$ and $\Omega_\Lambda = 0.73$, is adopted throughout the paper.

2 PROPERTIES OF THE SAMPLE AND BROADBAND SED MODELING

2.1 Sample Selection and Properties

The AGN sample used in this paper is reported in Paper-I, based on the cross-correlation of SDSS DR7 and XMM-Newton catalogs. The complete source list, detailed sample selection criteria and sample properties can be found in Paper-I. The main selection steps are summarized below:

- (1) We searched the 2XMMi and SDSS DR7 catalogs and identified 3342 extragalactic sources having both X-ray and optical spectra.
- (2) Within these sources, we selected those with $H\beta$ in emission and redshift $z < 0.4$, so that both the $H\alpha$ and $H\beta$ emission lines are covered by the SDSS spectra. This assists with modelling of the Balmer lines (see Paper-I). This selection resulted in 802 unique X-ray sources.
- (3) Within this subsample, we identified 96 Type 1 AGNs all with a minimum of 2000 counts in at least one of the three XMM-Newton EPIC cameras, to ensure high X-ray spectral quality.
- (4) We then excluded 23 sources whose $H\beta$ line was modified due to high reddening, low S/N or a data gap in the SDSS spectra. The resulting sample contains 73 AGNs.
- (5) For each of the 73 sources, a power law model was fitted to the rest-frame 2-10 keV X-ray spectra. The 16 objects with photon index uncertainties greater than 0.5

were excluded, leaving 57 Type 1 AGNs with relatively well constrained 2-10 keV spectra.

- (6) A further 6 objects were excluded because of an obvious signature of a warm absorber at $\sim 0.7\ keV$. This criterion means that the observed spectra are very likely directly related to emission from the bare central core.

The final sample contains 51 AGNs, with 12 AGNs classified as NLS1 using the conventional definition (Goodrich 1989), while the others are all BLS1s. The BAL quasar PG 1004+130 is also included in our sample whose weak and featureless X-ray emission is still under debate (Miller et al. 2006). The vast majority of the sample are radio-quiet with only three radio-loud sources i.e. PG 1004+130, RBS 0875 and PG 1512+370.

The $H\beta$ FWHM of the sample ranges from $600\ km\ s^{-1}$ to $13000\ km\ s^{-1}$.

2.2 The Spectral Modelling

Based on the high quality spectra, Paper-I conducted detailed spectral analysis for each source in the sample. In the optical spectral fitting, the $H\alpha$ and $H\beta$ lines were fitted using three components. The narrow component has the same profile as the entire [OIII] $\lambda 5007$ line, i.e. including both the central and blue component in [OIII] $\lambda 5007$. The intermediate and broad components are assumed have the shape of a Gaussian. All other strong nearby emission lines are included by adding more Gaussian profiles into the whole model. Then a complete model with multiple components were used to fit the whole SDSS spectra, including the underlying continuum approximated by a power law, the Balmer continuum, the FeII ‘false’ continuum and all strong emission lines. The broadband SED model used in Paper-I (*optcagn*, hereafter: Model-A) consists of the following three continuum components: 1. emission from a modified standard accretion disc, whose energy within the corona radius is completely reprocessed into the other two high energy Comptonisation components. 2. emission from the low temperature, optically thick Comptonisation, which mainly accounts for the soft X-ray excess. 3. emission from the high temperature, optically thin Comptonisation which gives the power law shape of the hard X-ray spectrum above 2 keV.

Figure 1. An example of the broadband SED fitting using *optxagnf* model in *Xspec* v12 which includes the effect of a colour correction. The data is taken from SDSS and XMM-Newton observations of RBS 769. The solid red line shows the total model; the dashed green line shows the colour corrected and truncated accretion disc emission; the dotted orange line shows the low temperature optically thick Comptonisation; the dot-dash blue line shows the high temperature optically thin Comptonisation. The reduced χ^2 is 1.16 for this spectral fitting.

Both Galactic extinction and the small amount of intrinsic reddening/extinction are included in the model.

Because the model was in the process of development, Paper-I did not consider the effect of a colour temperature correction in the accretion disc model (e.g. Ross, Fabian & Mineshige 1992; Davis & Hubeny 2006). This effect is due to the fact that the absorption opacity decreases significantly as the black hole mass increases ($\kappa_{abs} \propto M^{-1/8}$, Done et al. 2011), so for the same Eddington ratio, AGN’s disc has a lower absorption opacity than BHB. Then for some AGNs the accretion disc may no longer be locally thermalised. The higher temperature photons can emerge from regions deeper in the disc, and so the disc spectrum extends to higher energy than for standard accretion disc spectrum, producing the effect of a colour temperature correction. However, this can only happen for disc regions of $T > 3 \times 10^4$ K where sufficient hydrogen atoms are ionized. In addition, the electron scattering opacity also becomes important in these regions. The lower energy electrons in the surface regions Compton down-scatter the higher temperature photons from deeper disc regions, thus reducing the colour temperature correction. These two competing effects lead to an effective colour temperature correction (Davis et al. 2006).

The maximum effective temperature of the accretion disc is $kT \sim 10(\dot{m}/M_8)^{1/4}$ eV (where $\dot{m} = L_{bol}/L_{Edd}$, $M_8 = M/10^8 M_\odot$), so only for AGNs with low mass black holes and high mass accretion rates such as the NLS1s (e.g. Boller, Brandt & Fink 1996; Paper-I), electron scattering opacity will dominate, and the effect of colour temperature correction becomes important. A typical colour tem-

perature correction of 2.6 is predicted for an AGN with $M_{BH}=10^6 M_\odot$, $\lambda_{Edd}=1.0$ (Davis, Done & Blaes 2006; Done et al. 2011). This effect combines with an already hot disc due to the low black hole mass, resulting in a disc spectrum that extends significantly into the soft X-ray range.

A more detailed explanation of this colour temperature correction in AGN can be found in Done et al. (2011), where a model (*optxagnf* in *Xspec* v12) is proposed which applies a colour temperature correction for the Comptonised accretion disc model (hereafter: Model-B). In this paper we use this more advanced model to fit the optical, UV and X-ray data so as to construct the broadband SED for each source. Figure 1 shows an example of the broadband SED fitting to the multi-waveband spectra of RBS 769. A detailed description of Model-B in comparison with the earlier model *optxagn* (Model-A), can be found in Done et al. (2011). The set of fitting parameters for each source, based on Model-B, is given in Table B1. Section 6.3 discusses the statistical differences resulting from using Model-B and Model-A for our sample.

All the principal SED parameters such as λ_{Edd} , $\kappa_{2-10keV}$ and α_{ox} are calculated from the new model fitting (see Table B2). A cross-correlation study of the various parameters is then conducted. In Table 1 we compare the mean values of some SED parameters of our sample with those samples used in previous work. The result of correlations established in these previous studies will be compared with ours in the following sections.

There are two sources that we treated as being anomalous in our study. The first is PG 1004+130, a broad absorption line (BAL) quasar, whose X-ray was reported as being extraordinarily weak. Although its X-ray spectrum does not show clear absorption edges, it is nevertheless likely to be heavily absorbed, so that the remaining X-rays may have a different origin such as a sub-parsec-scale jet. It has been suggested that the X-ray emission from PG 1004+130, after correcting for its intrinsic absorption, is 0.73 dex weaker than normal PG radio loud quasars (PG RLQs) normalized to similar optical/UV luminosities (Miller et al. 2006). Due to its distinct X-ray spectrum (and correspondingly different X-ray parameters), we did not include this source in our regression analysis. The other anomalous source is Mrk 110. This source shows strong optical variability (Kollatschny et al. 2001; Kollatschny 2003) and its SDSS spectrum has a different slope from the (non-simultaneous) XMM-Newton OM data (see Paper-I). However, the optical spectrum obtained using FAST shown in Landt et al. (2011), is consistent with the OM data, and is also an order of magnitude more brighter than the SDSS spectrum. Therefore the SDSS spectrum of Mrk 110 is not consistent with its broadband SED parameters, and so we exclude Mrk 110 from any correlation which depends on optical parameters, but include it for any UV/X-ray correlations.

3 INVESTIGATING THE CORRELATIONS FOR VARIOUS SED PARAMETER GROUPS

In this section we divide the SED parameters into several sub-groups, based on correlations reported in the literature (see Section 1), and then perform a cross-correlation analysis within each group.

Table 2. Comparison of regression line coefficients for L_{2keV} , L_{2500} , α_{ox} and redshift Correlations. Lusso10: Lusso et al. (2010); Grupe10: Grupe et al. (2010); Green09: Green et al. 3.1 Group 1: L_{2500} , L_{2keV} and α_{ox}

The α_{ox} index has been used as the indicator of the SED shape for more than thirty years. It is often used as an indication of the AGN's broadband SED, and to convert between the AGNs' optical luminosity function (OLF) and X-ray luminosity function (XLF) (e.g. Hopkins, Richards & Hernquist 2007, hereafter: Hopkins07; Tang, Zhang & Hopkins 2007, hereafter: Tang07).

Many studies have been carried out on the evolution of α_{ox} with luminosity (e.g. Avni & Tananbaum 1982; Wilkes et al. 1994; Strateva et al. 2005; Steffen et al. 2006; Just et al. 2007; Green et al. 2009, hereafter: Green09; Lusso10; Grupe10), which may provide clues on the emission mechanism. The value of α_{ox} has been found in the range 1.2~1.8, with a mean value of ~1.5. Correlations have also been found between L_{2keV} , L_{2500} and α_{ox} , with the primary correlation being $L_{2keV} \propto L_{2500}^\beta$. The slope index β was often found to deviate from unity for both optically selected (e.g. Strateva et al. 2005; Steffen et al. 2006; Just et al. 2007) and X-ray selected AGN samples (e.g. Lusso10). However, La Franca, Franceschini & Cristiani (1995) re-analyzed Wilkes et al. (1994)'s sample by considering both variables and intrinsic scattering, and found that β was consistent with unity. Green09 collected a large, well-defined sample of 2308 SDSS/ChAMP QSOs in the redshift range 0.2~5.4, and concluded that β is not less than unity.

The reality of a non-linear correlation in L_{2keV} vs. L_{2500} remains an open question, but one possible explanation could be a selection effect in a flux limited sample for which dispersions in the optical and X-ray luminosity are not equal, or which change with cosmic time (Yuan, Siebert & Brinkmann 1998, hereafter: Yuan98; Tang07). However, the possibility of a truly intrinsic non-linear correlation cannot be ruled out. A non-linear L_{2keV} vs. L_{2500} correlation implies that there is a dependence of α_{ox} on L_{2keV} and L_{2500} (e.g. Vignali, Brandt & Schneider 2003; Just et al. 2007; Lusso10), but this is still a matter of debate (Yuan98; Tang07).

To further test the basis of these correlations, we also calculated the values of L_{2keV} , L_{2500} and α_{ox} from our best-fit model of the SEDs, and then performed the same cross-

correlation analysis. The limitation of our results arises from the lack of actual spectral coverage at 2500Å for the 16 sources without OM UVW1 and UVM2 data. The luminosity and redshift range of our sample is also relatively small. But on the merit side we have included two inputs of reddening/absorption to model both the Galactic and the AGN's intrinsic extinction during the broadband SED fitting, so our values of L_{2keV} , L_{2500} and α_{ox} should be closer to those of the intrinsic source. The unobscured nature of our sample and the exclusion of warm absorber sources also helps reduce uncertainties in the corrections caused by reddening/absorption.

3.1.1 The L_{2keV} vs. L_{2500} Correlation

Figure 2 shows our L_{2keV} vs. L_{2500} correlation. The statistical methods used are the same as in Lusso10, i.e. we use the full parametric estimate and maximized regression (EM) algorithm. We use this to derive two regression lines assuming, first L_{2keV} , then L_{2500} to be the independent variable. Then the bisector of the two regression lines is calculated using the equations in Isobe et al. (1990). This method is more appropriate in cases where the cross-correlations are dominated by intrinsic scatter. The correlations found are as follows:

(i) the EM regression line, when L_{2500} is assumed to be the independent variable:

$$\text{Log}(L_{2keV}) = (0.83 \pm 0.05) \text{Log}(L_{2500}) + (1.59 \pm 1.55) \quad (1)$$

(ii) the EM regression line, when L_{2keV} is assumed to be the independent variable:

$$\text{Log}(L_{2keV}) = (1.09 \pm 0.09) \text{Log}(L_{2500}) - (6.17 \pm 2.66) \quad (2)$$

(iii) the bisector of the above two regression lines (the solid orange line in Figure 2)

$$\text{Log}(L_{2keV}) = (0.95 \pm 0.06) \text{Log}(L_{2500}) - (2.04 \pm 1.77) \quad (3)$$

The Spearman's rank test gives a rank coefficient of $\rho_s = 0.87$, and the probability of deviation from a random distribution is $d_s = 1.2 \times 10^{-16}$, confirming a very high level

Figure 2. The cross-correlation between L_{2500} and L_{2keV} . The solid orange line is the bisector regression line for our sample. The red triangle symbols represent NLS1s; purple symbols show the radio loud AGN; the blue square symbol is Mrk 110. The filled purple star is the BAL-quasar PG 1004+130, and the open purple star is the position if its intrinsic X-ray flux was 0.73 dex higher (Miller et al. 2006). All triangle symbols represent Population A sources whose $H\beta$ FWHM is less than 4000 km s^{-1} . In the two histograms the green and red regions are for the Population A sources, and the red region indicates the 12 NLS1s. The dashed green line is based on Hasinger05; the dash-dotted cyan line is based on Green09; the dotted pink line is based on Lusso10.

of significance. We superimpose PG 1004+130 (filled purple star) on Figure 2, showing that it lies far from the correlation due to its unusual X-ray weakness. It matches much better to the regression line if corrected in L_{2keV} by 0.73 dex (Miller et al. 2006, the empty purple star in Figure 2).

Our correlation between L_{2keV} vs. L_{2500} is close to linear, but previous studies have found a wide range of values as listed in Table 2.2. Figure 2 plots these results for comparison. The correlation found by Hasinger05 (green dashed line) which is based on an X-ray selected sample, is the most consistent with our sample, whereas the slope found by Lusso10 (pink dashed line) is significantly flatter. Our slope is also consistent with Green09 (cyan dashed line) in which a large sample of optically selected quasars is analyzed. We note that our sample only covers the low luminosity region of the sample in Green09. The NLS1s are the least luminous sources. The different value of the Y-axis intercept in Green09 may be due to their larger sample and larger luminosity dispersion.

There can be several reasons for the difference between our results and Lusso10. Firstly there may be a selection effect of a flux limited sample if there are different amounts of dispersion in optical and X-ray luminosities (Yuan98; Tang07). More importantly, our sample is corrected for both Galactic and intrinsic reddening/absorption in the host Galaxy through the spectral fitting whereas that of Lusso10

is only corrected for Galactic absorption. We remove the intrinsic reddening correction and re-compute the EM regression, with results given in Table 2.2 under the row ‘This Work- r_{int} ’. The dust reddening and gas absorption column are related by, $E(B-V) = 1.7 \times (N_H/10^{22}) \text{ cm}^{-2}$ (Bessell 1991), which means that L_{2500} is suppressed much more severely than L_{2keV} . Hence the removal of intrinsic reddening correction decreases our correlation slope from $0.95 (\pm 0.06)$ to $0.91 (\pm 0.05)$. Thus the intrinsic reddening can flatten the correlation, but it does not seem to be enough on its own to explain the difference with Lusso10, unless their sample is strongly reddened in the optical.

3.1.2 The α_{ox} vs. L_{2keV} and L_{2500} Correlations

To further investigate the correlation between the optical/UV and X-ray continua, we adopt the same approach as in previous work to produce α_{ox} vs. L_{2500} and α_{ox} vs. L_{2keV} correlations. If we assume $L_{2keV} \propto L_{2500}^\beta$, then $\alpha_{ox} \propto L_{2500}^{1-\beta}$ and $\alpha_{ox} \propto L_{2keV}^{\beta(1-\beta)}$ are expected by definition. However, the Spearman’s rank test does not imply very strong correlations: $\rho_s = 0.31, d_s = 0.03$ for α_{ox} vs. L_{2500} ; $\rho_s = -0.13, d_s = 0.35$, for α_{ox} vs. L_{2keV} . The regression lines were derived but with large uncertainty. The results are presented in Figure 3 and listed in Table 2.2. The solid orange line in each panel of Figure 3 is our EM regression line, compared with some previous work shown by dashed lines. Note that our results are limited to redshift $z < 0.4$, $L_{2500} < 10^{+31} \text{ erg s}^{-1} \text{ Hz}^{-1}$ and $L_{2keV} < 10^{+27.5} \text{ erg s}^{-1} \text{ Hz}^{-1}$. Our results also suggest that the cross-correlations in α_{ox} vs. L_{2500} and L_{2keV} are dominated by the AGN’s intrinsic dispersion.

3.2 Group 2: α_{ox} , $\kappa_{2-10keV}$ and λ_{Edd}

As mentioned in the previous section α_{ox} is often used as a proxy for the broadband SED shape. Since L_{bol} is often dominated by the big blue bump (BBB) peaking in the unobservable EUV region (Walter & Fink 1993). $\kappa_{2-10keV}$, defined as $L_{bol}/L_{2-10keV}$, is also an indicator of the SED shape. λ_{Edd} is an important parameter which relates directly to the accretion processes close to the central SMBH. Therefore, correlations are to be expected between λ_{Edd} , $\kappa_{2-10keV}$ and α_{ox} .

3.2.1 The α_{ox} vs. $\kappa_{2-10keV}$ Correlation

Lusso10 reported a tight second-order polynomial correlation for $\kappa_{2-10keV}$ vs. α_{ox} . We find a similar correlation for our sample. Spearman’s rank test shows $\rho_s = 0.73$ and $d_s = 2 \times 10^{-9}$. We also fitted a second-order polynomial to the correlation and obtained the following equation:

$$\text{Log}(\kappa_{2-10}) = (5.7 \pm 3.4) - (8.8 \pm 5.2)\alpha_{ox} + (4.3 \pm 2.0)\alpha_{ox}^2 \quad (4)$$

Figure 4 shows our best-fit polynomial (solid orange line) with $\pm 1\sigma$ dispersion region (the shaded region). Note that our fit excludes BAL quasar PG 1004+130 (purple star in Figure 4). The best-fit polynomial from Lusso10 is plotted as the dashed green line, which is not as steep as ours. The reason is that our value of $\kappa_{2-10keV}$ (and L_{bol}) is higher than found by Lusso10, especially for the narrow line objects (the

Figure 3. α_{ox} vs. L_{2500} and L_{2keV} . Each symbol represents the same type of source as in Figure 2. In each panel the solid orange line is the OLS regression line for our sample, assuming the X-axis variable to be the independent variable. The dash-dotted blue line is based on Steffen06; the dotted pink line on Green09; and the dashed green line on Lusso10.

Figure 4. $\kappa_{2-10keV}$ vs. α_{ox} . Each symbol represents the same type of source as in Figure 2. The solid orange line is the best fit line found using a second order polynomial, and the shaded area is the $\pm 1\sigma$ zone.

average $\kappa_{2-10keV}$ for our 12 NLS1s is 86^{+96}_{-45}). Lusso10 constructed their broadband SEDs by first assuming a power law extending from the optical to $500\text{\AA}$, then connecting the continuum at $500\text{\AA}$ linearly to that at 1 keV, and finally by extrapolating from 1 keV towards higher energies, using an exponentially cut-off power law. This model substantially underestimates L_{bol} for narrow line objects because such objects often have strong soft-X-ray excesses which contain a large fraction of the L_{bol} (Middleton et al. 2009; Jin et al. 2009; Paper-I). Our detailed broadband SED fitting has

modeled this soft-excess feature by including a low temperature optically thick Comptonization component. We claim that this results in a more accurate estimate of L_{bol} (Paper-I). So certainly for the nearby Type 1 AGNs (redshift < 0.4), the $\kappa_{2-10keV}$ vs. α_{ox} correlation we find should be more reliable. How the correlation behaves at high redshift requires further study, but Lusso10 has shown that such a second-order polynomial correlation still holds for Type 1 AGNs up to redshifts $z = 4$.

3.2.2 The α_{ox} vs. λ_{Edd} Correlation

The existence of a correlation of α_{ox} vs. λ_{Edd} remains unclear. VF07 found no correlation between these quantities, and so they proposed that α_{ox} did not provide useful information on the broadband SED shape. S08 confirmed VF07's result for their sample of 35 moderate to high luminosity radio-quiet AGN. On the contrary, Lusso10 did find a correlation between α_{ox} and λ_{Edd} , although with a large dispersion. This was confirmed by Grupe10 for their sample containing 92 soft X-ray selected AGNs, but their correlation was both flatter and stronger than that of Lusso10. We use our sample to investigate this situation, and our results are shown in Figure 5. The Spearman's rank test gives $\rho_s = 0.35$ and $d_s = 1 \times 10^{-2}$, suggesting that a correlation does exist. We then applied the ordinary least squares (OLS) regression, assuming λ_{Edd} to be the independent variable, and found the following relation:

$$\alpha_{ox} = (0.079 \pm 0.038) \log(\lambda_{Edd}) + (1.384 \pm 0.029) \quad (5)$$

In Figure 5 we show our results. Our correlation has less dispersion than found by VF07 and Lusso10, but has larger dispersion than that from Grupe10. The exclusion of a correlation is at the $\sim 2\sigma$ significance level, which is less significant than in Grupe10. Our regression line slope is consistent with, but slightly flatter, than that in Lusso10 ($\beta = 0.133 \pm 0.023$) and Grupe10 ($\beta = 0.11 \pm 0.02$). This is partly because our estimation of L_{bol} is higher than in previous studies, due to

Figure 5. λ_{Edd} vs. α_{ox} . Each symbol represents the same type of source as in Figure 2. The solid orange line is the bisector regression line determined by our sample. The cyan crosses are the binned data points of our sample. The dashed green line is from Lusso10; the dash-dotted purple line is from Grupe10.

the inclusion of a soft X-ray excess in our model. Therefore our value of λ_{Edd} is also higher for the NLS1s and other relatively narrow line objects. Another reason could be a selection effect. We have shown in the previous section that α_{ox} has a luminosity dependence, thus at higher redshift we tend to detect more luminous sources with steeper α_{ox} . While both our sample and Grupe10's have low redshifts (us: $z < 0.4$; Grupe10: $z < 0.3$), Lusso10's sample covers a much larger range in redshift ($0.04 < z < 4.25$), and indeed Lusso10's sample contains many objects with $\alpha_{ox} > 1.5$ and $z > 0.4$, which populate the empty region above $\alpha_{ox} = 1.5$ in Figure 5, and create a larger dispersion. The large dispersion observed in our study and previous work suggest that one should be cautious about using the α_{ox} vs. λ_{Edd} relation, because the λ_{Edd} inferred by α_{ox} may contain considerable uncertainties.

3.2.3 The $\kappa_{2-10keV}$ vs. λ_{Edd} Correlation

Wang, Watarai & Mineshige (2004) reported the correlation between $\kappa_{2-10keV}$ and λ_{Edd} , which was later confirmed by VF07,09. Most recently, Lusso10 also found this correlation for the 545 X-ray selected type 1 AGNs from the XMM-COSMOS survey. They suggested that the observed step change in this correlation does not result from the L_{bol} dependence on both $\kappa_{2-10keV}$ and λ_{Edd} . In our study we also find that λ_{Edd} is correlated with $\kappa_{2-10keV}$. A Spearman's rank test resulted in $\rho_s = 0.60$, $d_s = 5 \times 10^{-6}$ for the whole sample, and $\rho_s = 0.60$, $d_s = 5 \times 10^{-6}$ for the 12 NLS1s. Figure 6 shows our results, together with the results from VF07,09 and Lusso10. We performed an EM regression analysis and derived the following equations:

Figure 6. λ_{Edd} vs. $\kappa_{2-10keV}$. Each symbol represents the same type of source as in Figure 2. The solid orange line is the bisector regression line determined for our sample. The binned data points are from VF07 (pink) and VF09 (blue). The dashed green line is from Lusso10.

(i) An EM regression with λ_{Edd} being the independent variable

$$\text{Log}(\kappa_{2-10}) = (0.482 \pm 0.088) \text{Log}(\lambda_{Edd}) + (1.840 \pm 0.071) \quad (6)$$

(ii) An EM regression with $\kappa_{2-10keV}$ being the independent

$$\text{Log}(\kappa_{2-10}) = (1.179 \pm 0.166) \text{Log}(\lambda_{Edd}) + (2.232 \pm 0.090) \quad (7)$$

(iii) bisector of the above two lines (solid orange line in Figure 6):

$$\text{Log}(\kappa_{2-10}) = (0.773 \pm 0.069) \text{Log}(\lambda_{Edd}) + (2.004 \pm 0.049) \quad (8)$$

Our regression lines are highly consistent with the binned points from VF07,09 and also the regression line reported by Lusso10. The two lowest data bins from VF07,09 seem to have a relatively high deviation from the correlation lines, which may imply a change in slope of the correlation for sources with $\lambda_{Edd} < 0.01$. But we cannot test this possibility from our data due to the exclusion of sources with low λ_{Edd} resulting from our sample selection (Paper-I).

The results show that the $\kappa_{2-10keV}$ vs. λ_{Edd} correlation extends up to high $\kappa_{2-10keV}$ (~ 100) and super Eddington accretion rates (~ 10); such objects are mainly NLS1s (red square symbols in Figure 6) and some other relatively narrow line sources (black square symbols). We also note that the dispersion in our regression line is smaller than that in VF07,09 and Lusso10, in spite of the different methods used in deriving L_{bol} and the different redshift ranges. This suggests that the dispersion observed in the correlation is intrinsic. In Figure 6, we see that PG 1004+130 (filled purple star) deviates far from the regression line (also more than 3σ from VF07,09's binned data points), confirming its anomalously weak $L_{2-10keV}$. Increasing its $L_{2-10keV}$ by 0.73 dex

Figure 7. κ_{5100} vs. λ_{Edd} and $\kappa_{2-10keV}$. Each symbol represent the same type of source as in Figure 2. In the left panel, the solid orange line is the OLS line assuming λ_{Edd} to be the independent variable. The two dashed orange lines show the $\pm 1\sigma$ region, and the shaded region is the $\pm 2\sigma$ region. The blue open square symbol is Mrk 110 reported by Landt et al. (2011), which is connected by the blue dashed line to the filled blue square point measured from SDSS spectrum. The vertical and horizontal purple lines are for $\kappa_{5100}=9$ and $\lambda_{Edd}=1$. The symbols and lines in the right panel have the same meaning as those in the left panel.

(open purple star) moves it much closer to the correlation line.

3.3 Group 3: κ_{5100} , λ_{Edd} and $\kappa_{2-10keV}$

The 5100Å monochromatic continuum luminosity (L_{5100}) is often used to estimate L_{bol} , particularly for very large samples of AGN, when broadband SED modeling for every source is not practical. The conventional method is to use a constant scaling factor $\kappa_{5100} = 9$ (Kaspi et al. 2000; Richards et al. 2006: 10.3 ± 2.1), or κ_{5100} value that is anti-corrected with L_{bol} (Marconi et al. 2004, hereafter: Marconi04). VF07 showed that for high λ_{Edd} sources such as many of the NLS1s, there is a clear deviation from constant $\kappa_{5100} = 9$. In addition, potential contamination from the host galaxy will introduce dispersion into the κ_{5100} vs. λ_{Edd} correlation for low luminosity sources. However, this should not be a severe problem for our sample since in our sample host galaxy is not dominating (Paper-I). In our study a much stronger correlation was found in κ_{5100} vs. λ_{Edd} as the Spearman's rank test gives $\rho_s=0.81$ ($d_s=4 \times 10^{-13}$). Motivated by the strong correlations between λ_{Edd} and $\kappa_{2-10keV}$, we also found a strong correlation between κ_{5100} and $\kappa_{2-10keV}$, with a Spearman's rank test of $\rho_s=0.64$ ($d_s=9 \times 10^{-7}$).

The left panel of Figure 7 shows the correlation between κ_{5100} and λ_{Edd} . The solid orange line is the OLS regression line, the two dashed orange lines show the $\pm 1\sigma$ region, and the shaded region is the $\pm 2\sigma$ region. For a specific λ_{Edd} value, the 1σ dispersion of κ_{5100} is ~ 0.17 dex. The binned data points from VF07 are also shown in the plot for comparison. VF07's results are consistent with ours within $\pm 2\sigma$, but our correlation is much stronger. This may be attributed to the high spectral quality of our sample and the carefully de-

rived κ_{5100} and λ_{Edd} , based on our detailed broadband SED fitting. It also shows that the distribution of κ_{5100} peaks at $10 \sim 20$, with a 1σ dispersion of 0.29 dex. For the NLS1s, the mean κ_{5100} increases to 20 ($1\sigma = 0.23$ dex). This means that using a $\kappa_{5100} = 9$ (the horizontal purple line in the left panel Figure 7) would underestimate the intrinsic L_{bol} and λ_{Edd} , especially for samples containing sources with high λ_{Edd} e.g. the NLS1s. The OLS regression line that assumes λ_{Edd} to be the independent variable can be expressed by the following equation:

$$\text{Log}(\kappa_{5100}) = (0.467 \pm 0.045) \text{Log}(\lambda_{Edd}) + (1.430 \pm 0.027)(9)$$

We superimpose the SDSS and FAST (Landt et al. 2011) data from Mrk 110 (filled and open green square, respectively) on Figure 7. This shows the large optical variability in the spectrum. The FAST data is much more consistent with the XMM-Newton OM and also matches very well with the regression line. This supports the reliability of the correlation.

The strong correlation between κ_{5100} and $\kappa_{2-10keV}$ (shown in the right panel of Figure 7) is an expected result, given that both κ_{5100} and $\kappa_{2-10keV}$ strongly correlate with λ_{Edd} . Such a correlation is also reasonable considering the strong correlation between $L_{2-10keV}$ and L_{5100} (Paper-II). The 1σ dispersion of $\kappa_{2-10keV}$ is 0.40 dex, which is larger than that 0.29 dex for κ_{5100} . The $\pm 1\sigma$, $\pm 2\sigma$ zones are also shown in the Figure. The bisector regression line can be expressed by the following equation:

$$\text{Log}(\kappa_{5100}) = (0.593 \pm 0.053) \text{Log}(\kappa_{210}) + (0.239 \pm 0.086)(10)$$

Mrk 110 and PG 1004+130 are superimposed on the plot, and their corrected positions are much more consistent with the regression lines.

Marconi04 proposed that κ_{5100} anti-correlated with L_{bol} , but our study does not support such an anti-correlation, although our sample only occupies the L_{bol} region above $10^{10.7} L_{\odot}$ in Fig. 3 left panel of Marconi04. A Spearman's rank test for our sample gives $\rho_s=0.12$ ($d_s=0.39$), suggesting no correlation. The sources lying between $10^{11} \sim 10^{12.5} L_{\odot}$ have a mean $\kappa_{5100} = 16$, with a 1σ dispersion of 0.29 dex. So we find that our κ_{5100} values for these objects are much higher than reported in Elvis et al. (1994) and Marconi04.

3.4 Group 4: $\Gamma_{2-10keV}$, λ_{Edd} and $\kappa_{2-10keV}$

The strong correlation between 2-10 keV photon index ($\Gamma_{2-10keV}$) and λ_{Edd} has been studied in detail for the past ten years (e.g. Lu & Yu 1999; Wang, Watarai & Mineshige 2004; S06,08; Zhou10a). It is proposed that increasing the mass accretion rate leads to enhanced emission from the accretion disc, resulting in more seed photons from the disc, which then increases the Compton cooling of the corona, and softens the Comptonized hard X-ray spectrum, i.e. the slope of $\Gamma_{2-10keV}$ increases. It was also reported that both $\Gamma_{2-10keV}$ and λ_{Edd} strongly correlate with the FWHM of H β (e.g. Brandt, Mathur & Elvis 1997; S06,08; Grupe10), therefore these three parameters all strongly correlate with each other. However, S06,08 found that the correlation of $\Gamma_{2-10keV}$ vs. FWHM $_{H\beta}$ is weakened by the inclusion of highly luminous sources, but that the correlation of $\Gamma_{2-10keV}$ vs. λ_{Edd} still exists. This implies that the correlation of $\Gamma_{2-10keV}$ vs. λ_{Edd} is more fundamental. We also mentioned in Section 3.2 that the strong correlation between λ_{Edd} and $\kappa_{2-10keV}$ is confirmed, thus a strong correlation between $\Gamma_{2-10keV}$ and $\kappa_{2-10keV}$ is expected. Indeed, such a correlation has been reported recently by Zhou & Zhao (2010), hereafter: Zhou10b. In this section we carry out a similar cross-correlation study, to test the robustness of previous claims.

3.4.1 The Correlations and Regression Lines

The two panels in Figure 8 show our correlations between $\Gamma_{2-10keV}$, λ_{Edd} and $\kappa_{2-10keV}$. Table 3 summarizes the numerical results. Significant correlations are confirmed based on the Spearman's rank test: $\rho_s=0.40$ ($d_s=4 \times 10^{-3}$) for $\Gamma_{2-10keV}$ vs. λ_{Edd} , and $\rho_s=0.73$ ($d_s=4 \times 10^{-9}$) for $\Gamma_{2-10keV}$ vs. $\kappa_{2-10keV}$.

Following S08's approach, we applied the χ^2 minimization method for $\Gamma_{2-10keV}$ vs. λ_{Edd} correlation, assuming $\Gamma_{2-10keV} = \beta \text{Log}(\lambda_{Edd}) + \xi$. A typical error of 10% was assumed for λ_{Edd} . The small error in $\Gamma_{2-10keV}$ for Mrk 110 (the blue square symbol) caused the slope β to be 0.018 ± 0.019 , which is clearly not the best-fit line for the whole sample. We therefore excluded Mrk 110 and so found a more reasonable slope of 0.189 ± 0.026 , but this is still $\sim 5\sigma$ away from 0.31 ± 0.01 reported by S08 using the same method. It implies that the χ^2 minimization technique may not be an appropriate method for quantifying this correlation, because it can be strongly biased by sources with small error in the $\Gamma_{2-10keV}$ measurement (if the 2-10 keV spectrum has high S/N). The $\chi^2/\nu = 6.5$ in our fitting means that this correlation contains a big intrinsic dispersion along

Table 3. The line coefficients found using different regression methods for the correlations of $\Gamma_{2-10keV}$ vs. λ_{Edd} and $\kappa_{2-10keV}$.

		$\text{Log}(\lambda_{Edd})=\beta\Gamma+\xi$	$\text{Log}(\kappa_{210})=\beta\Gamma+\xi$
OLS(Y X)	β	0.918 ± 0.269	1.115 ± 0.172
	ξ	-2.325 ± 0.527	-0.573 ± 0.329
OLS(X Y)	β	4.730 ± 1.217	2.209 ± 0.283
	ξ	-9.650 ± 2.304	-2.675 ± 0.525
Bisector	β	1.753 ± 0.239	1.533 ± 0.153
	ξ	-3.931 ± 0.471	-1.376 ± 0.288
χ^2 min	β	4.416 ± 0.510	2.620 ± 0.184
	ξ	-8.761 ± 0.946	-3.447 ± 0.343
$\chi^2/\nu \sim 1$	β	1.274 ± 0.283	1.529 ± 0.183
	ξ	-3.003 ± 0.544	-1.372 ± 0.350

with the observational dispersion, thus the method of assuming $\chi^2/\nu \sim 1$ by taking intrinsic dispersion into account is more appropriate. This method gives slopes of 0.202 ± 0.061 and 0.226 ± 0.026 before and after excluding Mrk 110, so the results are less sensitive to individual sources of much smaller error bars. The intrinsic dispersion is 0.18, which is 86% of the total dispersion, and is also consistent with $\Delta\Gamma_{2-10keV} \sim 0.1 \times \Gamma_{2-10keV}$ reported in S08. The bisector regression line is derived. The result is plotted as a solid orange line in the left panel of Figure 8, and it can be expressed by the following equation:

$$\text{Log}(\lambda_{Edd}) = (1.773 \pm 0.238)\Gamma_{2-10keV} - (3.983 \pm 0.469) \quad (11)$$

The slope is $\sim 2\sigma$ steeper than the bisector slope of 0.9 ± 0.3 reported by S08 (dashed green line in the left panel of Figure 8). This discrepancy may be due to the different methods used to estimate the bolometric luminosity. We will discuss this point in Section 3.4.2.

Similar analytical methods were applied to the relation of $\Gamma_{2-10keV}$ vs. $\kappa_{2-10keV}$. Zhou10b reported a slope of 2.52 ± 0.08 , using standard χ^2 minimization and assuming $\kappa_{2-10keV} = \beta \text{Log}(\Gamma_{2-10keV}) + \xi$. This is consistent with our value of $\beta = 2.620 \pm 0.184$ with a $\chi^2/\nu = 2.78$. Considering the intrinsic scatter, Zhou10b reported a slope of 1.12 ± 0.30 by adding 0.32 dex of intrinsic dispersion to reduce χ^2/ν to unity (the dashed green line in the right panel of Figure 8). Applying the same method to our sample resulted in a slope of 1.529 ± 0.183 , which is steeper than found by Zhou10b. The intrinsic dispersion found by us is 80% of the total dispersion. The bisector regression method gives a slope of 1.533 ± 0.153 (the solid orange line in the right panel of Figure 8) and can be expressed by the following equation:

$$\text{Log}(\kappa_{2-10keV}) = (1.533 \pm 0.153)\Gamma - (1.376 \pm 0.288) \quad (12)$$

This is also consistent with the results found by assuming $\chi^2/\nu \sim 1$.

3.4.2 Advances from Our Correlation Analysis

Compared with the results found by S08 and Zhou10b, our study of $\Gamma_{2-10keV}$ vs. λ_{Edd} and $\kappa_{2-10keV}$ provides the following advances.

- (1) We have confirmed these correlations based on sample of twice the size of those in S08 and Zhou10b,

Figure 8. $\Gamma_{2-10\text{keV}}$ vs. λ_{Edd} and $\kappa_{2-10\text{keV}}$. Each symbol represents the same type of source as in Figure 2. In the left panel, the solid orange line is the bisector regression line. The dashed green line is that reported by Zhou10b. The vertical and horizontal purple lines are for $\Gamma_{2-10\text{keV}}=2$ and $\lambda_{\text{Edd}}=1$. The symbols and lines in the right panel have the same meaning as those in the left panel. The vertical purple line is for $\kappa_{2-10\text{keV}}=100$.

including more sources with high values of λ_{Edd} , $\Gamma_{2-10\text{keV}}$ and $\kappa_{2-10\text{keV}}$, which significantly extend the previous correlations (see Figure 8). The regression line fits are better constrained and cover wider parameter space. The difference between our regression lines and those of previous studies may be partially due to the fact that we have more sources of most extreme λ_{Edd} .

(2) Our sample has been carefully screened to exclude sources with a strong warm absorber. These sources may have $\Gamma_{2-10\text{keV}}$ and higher $\kappa_{2-10\text{keV}}$ artificially lower than the intrinsic values. Our sample quality is essential to reduce the dispersion and so reveal intrinsic correlations.

(3) Our estimates of L_{bol} were derived from the broadband SED fitting, which was based on high quality spectra and a new multi-component model. We claim this to be more reliable than the procedure used in previous studies. A conventional method is to apply a multiplication factor to L_{5100} to estimate L_{bol} . However, we showed in Section 3.3 that κ_{5100} is well correlated with λ_{Edd} , rather than being constant or dependent on L_{bol} , consequently the conventional scaling from L_{5100} to L_{bol} is likely to result in poor accuracy in some cases. The L_{bol} used in Zhou10b does come from VF09’s broadband SED model for the reverberation mapped sample, but it does not take account of the ‘soft X-ray excess’ component or where the disc peaks in the EUV. Therefore the L_{bol} we calculate will be larger than previous works, especially for those sources with a strong ‘soft excess’. Our λ_{Edd} and $\kappa_{2-10\text{keV}}$ will also be higher, which could account for the differences in slope between our regression lines and those reported in previous work.

3.5 Group 5: $\Gamma_{2-10\text{keV}}$, $H\beta$ FWHM and M_{BH}

3.5.1 The $\Gamma_{2-10\text{keV}}$ vs. $H\beta$ FWHM Correlation

The correlations between the soft/hard X-ray slopes and the Balmer line velocity width have been the subject of many previous studies. Puchnarewicz et al. (1992) studied 53 AGNs with ultra-soft X-ray excess and noticed that these ultra-soft AGNs tend to have narrower optical permitted lines. Laor et al. (1994) studied 23 ROSAT selected bright quasars, and found an anti-correlation between the 0.2-2 keV slope (α_X) and the $H\beta$ line width. Later Boller, Brandt & Fink (1996) showed that NLS1s tend to have softer X-ray spectra. Brandt, Mathur & Elvis (1997) extended this anti-correlation to include the 2-10 keV slope, by showing that NLS1s also have steeper hard X-ray continua than BLS1s, a result which was confirmed and extended by other studies (e.g. Grupe et al. 1999; Leighly 1999; Piconcelli et al. 2005; Brocksopp et al. 2006; S08; Zhou10a). However, there is large scatter within this correlation, and the trend seems to invert below $\sim 1000 \text{ km s}^{-1}$ for NLS1s (Zhou et al. 2006). The observed large scatter is to be expected since we know that it is not a single variable that determines the spectral slope in either the soft or the hard X-ray region. In the soft X-ray region, the extinction, a soft-excess component and a warm absorber will all influence the spectral shape, which would require very detailed modeling. The situation for the 2-10 keV region is somewhat less complicated since often a single power law dominates (e.g. Middleton, Done & Gierliński 2007), but a warm absorber and reflection may still modify the hard X-ray spectral shape. In summary, the true correlation can only be found when the intrinsic X-ray continuum is used.

Our sample selection has ensured that every object in the sample has high quality 2-10 keV spectra, without sig-

Figure 9. $\Gamma_{2-10\text{keV}}$ vs. FWHM of $H\beta$ and M_{BH} . In the upper left panel, a broken line is fitted to the sample using the minimum χ^2 method, with the break point chosen to be $\text{FWHM} = 4000 \text{ km s}^{-1}$ (the orange square point). S06,08 proposed the linear correlation between $\Gamma_{2-10\text{keV}}$ and $\text{Log}(H\beta \text{ FWHM})$ was not followed by their 10 extremely high luminosity sources, so we plot their sample as blue diamond symbols for comparison. In the right panel binned points are plotted with 1 standard error of $\Gamma_{2-10\text{keV}}$ in order to show the break points more clearly. The two red points only include the NLS1s, the two dark points are the broadest BLS1s. The cyan point is the binned point for the whole sample of S06,08. The blue point is the binned point for S06,08's sample but excluding LBQS 0109+0213 whose $\Gamma_{2-10\text{keV}}$ is anomalously low. 1E 1556+27.4 shown by the red circle is another source with $\Gamma_{2-10\text{keV}} < 1.5$. In the second row, the symbols all have the sample meaning as in the first row, the break point is chosen to be $\text{Log}(M_{BH}) = 8.0$ (the orange square point). We plot the linear regression line as the dashed orange line.

nificant cold gas absorption or a warm absorber (Paper-I). We confirm that there is an anti-correlation between $\Gamma_{2-10\text{keV}}$ and $H\beta$ FWHM, see Figure 9. The Spearman's rank test gives $\rho_s = -0.72$ ($d_s = 4.9 \times 10^{-9}$). The best-fit lines from Zhou10a are also plotted in Figure 9 as the cyan lines. Compared with their linear correlation in using $\text{FWHM}_{H\beta}$, we find that the linear correlation using $\text{Log}(\text{FWHM}_{H\beta})$ is better. Previous work also noted that the correlation may change form at $\sim 4000 \text{ km s}^{-1}$ (Sulentic et al. 2008). Therefore we fit a broken power law to the data points in the

left panel by assuming a break point at $\text{FWHM}_{H\beta} = 4000 \text{ km s}^{-1}$. Intrinsic dispersion will dominate this correlation as shown in previous studies (e.g. Grupe et al. 1999; Grupe10; Zhou10a), so we performed this fitting without considering the error in $\Gamma_{2-10\text{keV}}$ associated with each point, otherwise the fitting would be biased by the few points with best constrained $\Gamma_{2-10\text{keV}}$ rather than revealing the distribution of the whole sample. The best-fit parameters are shown below:

- (i) when $\text{FWHM}_{H\beta} \leq 4000 \text{ km s}^{-1}$,

Figure 10. M_{BH} vs. $H\beta$ FWHM. Note that the black hole mass M_{BH} was constrained by $H\beta$ FWHM and obtained from the broadband SED fitting (i.e. the $M_{BH, FIT}$ in Paper-I), rather than directly calculated from the $H\beta$ FWHM. The symbols used represent the different types of source as in Figure 2. The solid orange line is the OLS regression line, assuming $H\beta$ FWHM to be the independent variable. The shaded region is the $\pm 1\sigma$ region of the regression line. The cyan triangle shows the position of $(FWHM_{H\beta, break}, \text{Log}(M_{BH, break}))$ in Figure 9.

$$\Gamma = (-0.86 \pm 0.01) \text{Log}(FWHM_{H\beta}) + (4.89 \pm 0.03) \quad (13)$$

(ii) when $FWHM_{H\beta} > 4000 \text{ km s}^{-1}$,

$$\Gamma = (-0.11 \pm 0.01) \text{Log}(FWHM_{H\beta}) + (2.20 \pm 0.04) \quad (14)$$

Sources with $FWHM_{H\beta} > 4000 \text{ km s}^{-1}$ have an average $\Gamma_{2-10keV} = 1.78 \pm 0.12$. The only source included in the correlation whose $\Gamma_{2-10keV} < 1.5$, is 1E 1556+27.4, (the data for PG 1004+130 is superimposed but not used for the regression). A closer examination of the spectrum of this AGN shows that it probably has a strong reflection component modifying its intrinsic hard X-ray power law slope (Paper-I). All other objects have values consistent with $\Gamma_{2-10keV} > 1.5$. The differences in the results of Zhou10a and our work are not only because we performed our correlation fitting using $\text{Log}(FWHM_{H\beta})$, but also because their sample did not exclude BAL quasars and warm absorbers, whose low values of $\Gamma_{2-10keV}$ are probably not intrinsic. This will bias the correlation and increase the scatter.

Our sample includes six objects with $FWHM_{H\beta} > 10000 \text{ km s}^{-1}$. These are the sources have average $\langle \Gamma_{2-10keV} \rangle = 1.76 \pm 0.14$ independent of the $FWHM_{H\beta}$. This is slightly lower but still consistent with the $\Gamma_{2-10keV} = 1.97 \pm 0.31$ index found by S06,08, who included more high redshift, high luminosity sources, with $FWHM_{H\beta} > 10000 \text{ km s}^{-1}$.

3.5.2 The $\Gamma_{2-10keV}$ vs. M_{BH} Correlation

The $H\beta$ FWHM is frequently used to estimate the M_{BH} , using the relation $M_{BH} \propto FWHM_{H\beta}^2$ (Wandel, Peterson & Malkan 1999; Woo & Urry 2002). The correlation of $\Gamma_{2-10keV}$ vs. $FWHM_{H\beta}$ implies a similar correlation in $\Gamma_{2-10keV}$ vs. M_{BH} . This is confirmed in our study as shown in the second row of Figure 9. The Spearman's rank test gives $\rho_s = -0.3$ ($d_s = 3 \times 10^{-2}$). We also plot $FWHM_{H\beta}$ vs. M_{BH} in Figure 10. This is an independent plot as our M_{BH} are derived from the SED continuum fits rather than directly measured from $FWHM_{H\beta}$. The OLS regression gives $M_{BH} \propto FWHM_{H\beta}^{1.16}$, with a $1\sigma = 0.4$ dex. The cyan triangle symbol in the figure shows the position of the break in $FWHM_{H\beta}$ vs. M_{BH} . The correlation in Figure 10 suggests $FWHM_{H\beta} = 4000 \text{ km s}^{-1}$ corresponds to a black hole mass of $10^8 M_\odot$. Indeed, the correlation in the second row of Figure 9 shows a change in slope at $\text{Log}(M_{BH}) \sim 8.0$. A broken power law fitting, assuming the break point at $\text{log}(M_{BH}) = 8.0$, can be expressed as follows:

(i) when $\text{Log}(M_{BH}) \leq 8.0$,

$$\Gamma_{2-10keV} = (-0.372 \pm 0.005) \text{Log}(M_{BH}) + (4.802 \pm 0.037) \quad (15)$$

(ii) when $\text{Log}(M_{BH}) > 8.0$,

$$\Gamma_{2-10keV} = (0.056 \pm 0.007) \text{Log}(M_{BH}) + (1.380 \pm 0.052) \quad (16)$$

Sources with $\text{Log}(M_{BH}) > 8.0$ have an average $\Gamma_{2-10keV} = 1.86 \pm 0.21$.

3.6 Other Strong Correlations

The diverse correlations found in small parameter groups imply more correlations among all these parameters. We show some significant correlations in Figure 12. These include decreasing λ_{Edd} , $\kappa_{2-10keV}$, κ_{5100} with increasing $H\beta$ FWHM and M_{BH} . Binned data points are shown as cyan crosses. The dashed orange line in each panel is the bisector regression line.

3.6.1 The $\kappa_{2-10keV}$ vs. $L_{2-10keV}$ correlation

Marconi04 and Hopkins07 reported a strong positive correlation in $\kappa_{2-10keV}$ vs. $L_{2-10keV}$, based on a quasar SED template and the α_{ox} vs. L_{2500} correlation reported by Stefan et al. (2006). VF07 tested the same correlation in their low redshift AGN sample but found no correlation (see Figure 11). We tested this correlation in our sample and confirmed VF07's result (see Figure 11). A highly dispersed anti-correlation of $\kappa_{2-10keV}$ vs. $L_{2-10keV}$ is found in our study.

For the well sampled high X-ray luminosity region ($L_{2-10keV} > 10^{43} \text{ erg s}^{-1}$), both VF07 and our samples show very similar distribution and dispersion. NLS1s in both samples mainly populate the regions of $\kappa_{2-10keV} \gtrsim 100$ and $10^{42} \text{ erg s}^{-1} < L_{2-10keV} < 10^{43} \text{ erg s}^{-1}$, and deviate from the correlation suggested by Marconi04 and Hopkins07. The main difference from VF07 is that our sample have more sources within the range of $3 \times 10^{42} \text{ erg s}^{-1} < L_{2-10keV} < 10^{43} \text{ erg s}^{-1}$, while VF07 sample contains three extraordinary weak X-ray sources whose $L_{2-10keV} < 2 \times 10^{42} \text{ erg s}^{-1}$. Thus we think those intrinsically X-ray weak ($L_{2-10keV} \sim 10^{42} \text{ erg s}^{-1}$) sources may populate the low $L_{2-10keV}$, small

Figure 11. $\kappa_{2-10\text{keV}}$ vs. $L_{2-10\text{keV}}$. Different symbols represent the same type of sources as in Figure 2. The orange and gray shaded regions represent the theoretical $\kappa_{2-10\text{keV}}$ with $\pm 1\sigma$ scattering at each $L_{2-10\text{keV}}$ in Hopkins07 and Marconi04. The green data points are reproduced from Fig.3 in VF07.

$\kappa_{2-10\text{keV}}$ region, creating a totally dispersed distribution in the $\kappa_{2-10\text{keV}}$ vs. $L_{2-10\text{keV}}$ plot. The correlations from Marconi04 and Hopkins07 may have underestimated the uncertainties in using α_{ox} vs. L_{2500} correlation (see discussion in Section 3.1) and the universal quasar SED template (e.g. Elvis et al. 1994; VF07; Paper-I). However, we cannot rule out the possibility that the behaviors of nearby Seyfert AGNs are different from quasars at higher redshift.

3.6.2 α_{UV} and α_X related correlations

While $\Gamma_{2-10\text{keV}}$ is the 2-10 keV photon-index measured directly from the X-ray data, we can also measure the optical/UV slope and soft X-ray slope from our reconstructed SED. Assuming $F_\nu \propto \nu^{-\alpha}$, we define α_{UV} as the spectral slope between 1700-6500 Å (the *Swift* UVOT wavelength coverage), and α_X as the soft X-ray slope between 0.2-2 keV, so as to be comparable with the results in Grupe10. Note that we do not have complete OM data for every source, and we only use X-ray data from XMM-Newton above 0.3 keV, so our α_{UV} and α_X values are model dependent. The soft X-ray and optical/UV regions cannot be simply fitted by a single power law (see the SEDs in Paper-I), and thus α_{UV} and α_X are just rough estimates of the spectral shape. We measure α_{UV} and α_X from the best-fit SED in Paper-I corrected for Galactic and intrinsic reddening/absorption, and list the values in Table B2.

It was found previously that AGNs with bluer optical/UV spectra tend to have softer X-ray spectra (Walter & Fink 1993; Grupe et al. 1998; Grupe10). We found $\rho_s = -0.65$ ($d_s = 4 \times 10^{-7}$) for α_{UV} vs. $\Gamma_{2-10\text{keV}}$, and $\rho_s = -0.41$ ($d_s = 3 \times 10^{-3}$) for α_{UV} vs. α_X , so confirm

the results from other studies. We also tested the results of α_{UV} and α_X without correction for intrinsic reddening/absorption. The Spearman's rank coefficients remain similar which is because of the unobscured nature of our sample. Another correlation found in previous work is that AGNs with steeper X-ray spectra tend to be weak at hard X-ray energies (Atlee & Mathur 2009; Grupe10; but see also Young, Elvis & Risaliti 2009). This can be directly confirmed in our study by the anti-correlation found between α_X and $L_{2-10\text{keV}}$ ($\rho_s = -0.60$, $d_s = 6 \times 10^{-6}$), and the correlation between α_X and α_{ox} ($\rho_s = 0.65$, $d_s = 5 \times 10^{-7}$, Figure 13). However, we only find a marginal anti-correlation between α_{UV} and α_{ox} (see Table 4), which is much less significant than found by Grupe10. This seems to be due to the fact that our sample has few sources with $\alpha_{ox} > 1.6$ and $\alpha_{UV} < 0$.

Similar to the $\Gamma_{2-10\text{keV}}$ vs. λ_{Edd} correlation discussed in Section 3.4, α_X and α_{UV} were also found to (anti-)correlate with λ_{Edd} (Grupe 2004; S08; Grupe10). This is confirmed in our study as we find $\rho_s = 0.49$ ($d_s = 4 \times 10^{-4}$) for α_X vs. λ_{Edd} which is stronger than the correlation between $\Gamma_{2-10\text{keV}}$ and λ_{Edd} , and $\rho_s = -0.55$ ($d_s = 4 \times 10^{-5}$) for α_{UV} vs. λ_{Edd} . In addition, we also find strong (anti-)correlations such as α_X (or α_{UV}) vs. $\kappa_{2-10\text{keV}}$, α_X (or α_{UV}) vs. $\kappa_{5100\text{Å}}$, α_X (or α_{UV}) vs. $\text{FWHM}_{H\beta}$ and α_X (or α_{UV}) vs. M_{BH} (see Figure 13, Table 4).

4 A SYSTEMATIC CORRELATION STUDY ON THE KEY PARAMETERS

To summarize the various correlations discussed in the previous section, we performed a systematic correlation study of the following key parameters: $\Gamma_{2-10\text{keV}}$, $\kappa_{2-10\text{keV}}$, $\kappa_{5100\text{Å}}$, λ_{Edd} , $\text{FWHM}_{H\beta}$, M_{BH} , α_{ox} , L_{bol} , $L_{2-10\text{keV}}$, α_{UV} and α_X .

First, a correlation matrix was constructed as shown in Table 4. The Spearman's rank coefficient and probability of a null hypothesis are given. The table shows that there are some sub-groups of parameters which are strongly coupled with each other. For example, $\kappa_{2-10\text{keV}}$, $\kappa_{5100\text{Å}}$ and λ_{Edd} are coupled; $\Gamma_{2-10\text{keV}}$, $H\beta$ FWHM, α_X and $\kappa_{2-10\text{keV}}$ are also coupled with each other. The strong correlation between $H\beta$ FWHM and $\kappa_{2-10\text{keV}}$ can be expressed by the following equation derived from a bisector regression analysis:

$$\text{Log}(\kappa_{2-10}) = (-1.22 \pm 0.12) \text{Log}(\text{FWHM}) + (5.88 \pm 0.45) \quad (17)$$

There also appears to be a sub-group consisting of M_{BH} , L_{bol} and $L_{2-10\text{keV}}$, and a sub-group consisting of M_{BH} , $H\beta$ FWHM and $L_{2-10\text{keV}}$. However, correlations within these sub-groups are probably a result of selection effects arising from our sample selection criteria. For example, the inclusion of extremely weak $L_{2-10\text{keV}}$ sources may weaken or eliminate the correlations between $L_{2-10\text{keV}}$ and other parameters.

The observed properties of AGN should be ultimately driven by the black hole mass, mass accretion rate, black hole spin and orientation angle. We have assumed the simplest Schwarzschild black hole in our model and so its spin is not considered. Uncertainties introduced by orientation angle should also be small since our sample only contains unobscured Type 1 AGNs. Therefore, the remaining intrinsic parameters are just the black hole mass and mass accretion rate (or equivalently, Eddington ratio)

Figure 12. Examples of some good correlations not reported previously. In each panel the various symbols represent the same types of source as in Figure 2. The cyan symbols are the binned data points over the X-axis with a 1 standard error on the Y-axis.

Figure 13. Examples of some good correlations not reported previously. In each panel the various symbols represent the same types of source as in Figure 2. The cyan symbols are the binned data points over the X-axis with a 1 standard error on the Y-axis.

We can examine the correlations further by performing a principal component analysis (PCA) on the correlation matrix formed by Pearson's correlation coefficient (Pearson 1901; Boroson & Green 1992; Francis & Wills 1999). First, we include all the 11 parameters and so the dimension of the correlation matrix is 11. Therefore the outcome of the PCA must contain 11 normalized eigenvectors (principal compo-

nents: PCs), each associated with a positive eigenvalue. Each PC is a linear combination of the 11 parameters, and is orthogonal to all the other PCs. The sum of the 11 eigenvalues equals 11. A higher eigenvalue would suggest a larger fraction of correlations contained in the direction of the corresponding eigenvector.

guage) v6.2 was used to perform the PCA. We found that the first three eigenvectors contain 87% of the total correlations in the matrix, i.e. 53% in eigenvector 1 (PC1), 25% in eigenvector 2 (PC2) and 9% in eigenvector 3 (PC3). To determine the actual contributors of these eigenvectors, we cross-correlated them with the 11 key parameters. Table 5 lists the Spearman's rank coefficients. It is clear that PC1 correlates/anti-correlates very well with most key parameters, except for L_{bol} . The highest correlation strength is for $\kappa_{2-10keV}$, α_X and H β FWHM. These in turn are probably proxies for the physical variables of M_{BH} and λ_{Edd} . PC2 is dominated by L_{bol} which confirms that L_{bol} is a relatively independent variable. We have assumed that $L_{bol} = \mu \dot{M} c^2$, where μ is the standard accretion efficiency of 0.057 (see Paper-I), so PC2 is in effect dominated by the mass accretion rate $\dot{M}$. The contribution from the rest eigenvectors to the set of correlation is small compared to PC1 and PC2, and are therefore not important. It was also reported by Boroson (2002) that the PC1 from the correlation matrix of optical emission line parameters is driven predominantly by the Eddington ratio, while the PC2 from the same matrix is dominated by the luminosity. Therefore, the PC1 and PC2 from our correlation matrix of the 11 parameters have a similar basis to the two eigenvectors reported by Boroson (2002).

The inclusion of λ_{Edd} , M_{BH} and L_{bol} may bias the outcome of PCA, so we performed an independent PCA by

excluding λ_{Edd} , M_{BH} and L_{bol} from the correlation matrix (Grupe 2004; Grupe 2011), and so the remaining matrix only has a dimension of 8. The resultant eigenvectors were again correlated with each of the 11 parameters. The results are listed in Table 5. The two new principal eigenvectors (PC1-excl and PC2-excl in Table 5) are quite similar as PC1 and PC2 in terms of correlation outcomes with the 11 parameters. This confirms our previous PCA finding that the three physical parameters λ_{Edd} , M_{BH} and L_{bol} drive the majority of the correlations.

5 THE MEAN SEDS

5.1 Diversity of the Mean SEDs

In Paper-I we derived the mean SED for the 12 NLS1s in our sample, and compared this with the mean SEDs of another two groups of BLS1s. We showed that the SED shape changes dramatically as the H β FWHM increases. Since quasar SED are not uniform, modelling their spectra and evolution using a single template such as that of Elvis et al. (1994), will mask out a large dispersion in their intrinsic properties. In our study we aim to minimize this dispersion by grouping the SED based on each of the 11 key parameters discussed in the previous section. However, since α_{UV} and α_X are rough estimates of the spectral shape in optical/UV

Table 5. The cross-correlation of the eigenvectors with the 11 key parameters. The coefficients given are from the Spearman’s rank test. PC1 and PC2 are the principal components from the PCA on all the 11 parameters, while PC1-excl and PC2-excl are the principal components after excluding λ_{Edd} , M_{BH} and L_{bol} from the PCA. The row ‘Property’ shows the percentage of correlations contained in the direction of that eigenvector.

Property	PC1 53%	PC2 25%	PC1-excl 62%	PC2-excl 14%
$\Gamma_{2-10keV}$	0.71	0.03	0.75	-0.14
$\kappa_{2-10keV}$	0.93	0.14	0.94	0.06
κ_{5100A}	0.74	0.26	0.67	0.34
λ_{Edd}	0.60	0.67	0.51	0.60
H β FWHM	-0.89	0.17	-0.90	0.21
M_{BH}	-0.69	0.48	-0.65	0.34
α_{ox}	0.59	0.36	0.63	0.35
L_{bol}	-0.06	0.99	-0.10	0.81
$L_{2-10keV}$	-0.60	0.76	-0.65	0.67
α_X	0.92	-0.03	0.93	-0.01
α_{UV}	-0.74	-0.04	-0.70	-0.17

and soft X-ray regions, we excluded them from the mean SED calculation.

There are 51 AGNs in our sample. For each of the 9 remaining parameters, we sorted the sources according to the parameter value, and then classified the sample into three subsets so that each subset includes 17 sources. Then the BAL quasar PG 1004+130 was excluded from its subset. The SEDs constructed using Model-B in this paper were first corrected for redshift, and then divided into 450 energy bins between 1 eV and 100 keV in the logarithm. Within each subset we calculated the average luminosity in every energy bin in logarithm, together with the 1σ deviation. Then we derived the mean SED for each group together with the 1σ dispersion. The same calculation was repeated for each of the 9 parameters, so that there are three mean SEDs for each parameter. No special note was made for the NLS1s because their defining parameter, H β FWHM, is one of the 9 parameters.

Figure 14 shows our results. Each row displays the three mean SEDs divided according to the parameter shown in the panel title. The SEDs have all been renormalized to the mean luminosity at 2500Å of each subset. To highlight the differences among these SEDs, we mark the locations of 2500Å and 2 keV by the vertical orange lines. The relative height of these two lines directly reflects the value of α_{ox} , and the height of the bar at 2 keV shows the dispersion in α_{ox} since the co-added SED’s are all normalized at 2500Å. We also mark the energy peak for each mean SED by the vertical thick purple line. The mean values of other parameters are given in each plot for comparison.

We find that the mean SED changes in a similar way with all the parameters except L_{bol} . The energy at which the disc emission peaks decreases along with the ratio of luminosity in the disc compared to the Comptonised components, and the 2-10 keV spectral slope. Our stringent sample selection means that these spectral differences are intrinsic rather than due to absorption/extinction.

If the SED changes are determined solely by one of the parameters considered here, then binning based on that parameter should result in the minimum dispersion within each

individual binned SED, and maximal difference between the three SEDs spanning the range in that parameter. However, the SED changes should ultimately be physically dependent on changes in M_{BH} and λ_{Edd} . Since there are two dependent variables no single parameter will completely determine the behaviour. Hence the dispersion within each of the three binned SEDs is minimized (and the difference between them is maximized) for composite parameters which depend on both λ_{Edd} and M_{BH} such as $\kappa_{2-10keV}$, κ_{5100} and H β FWHM rather than the fundamental physical parameter λ_{Edd} . Future work with larger samples can improve on this study by selecting a subsample of AGN with different λ_{Edd} but similar M_{BH} . Such mass selected samples would give the best comparison to the SED changes in Black Hole Binaries (BHB), which all have the same mass to within a factor of ~ 2 .

5.2 Discussion of the Mean SEDs

Since our SED fitting is based on a physical model, we can ‘correct’ for the mass dependence of the SED shape to get an estimate for the SED differences in AGN as a function solely of λ_{Edd} . This is shown in Done et al. (2011) for a $M_{BH} = 10^8 M_\odot$ and forms the basis of a direct comparison with the BHB spectral states seen for these $M_{BH} = 10 M_\odot$ systems as λ_{Edd} changes. This has many superficial similarities to the dramatic state change seen in BHB as their luminosity increases. The SED changes from a ‘low/hard state’ being dominated by Comptonisation, with a hard X-ray spectral index $\Gamma_{2-10keV} < 2$, and the disc component peaking at rather low temperature, to a ‘high/soft state’ where the disc dominates the luminosity and the X-ray spectral index is softer, $\Gamma_{2-10keV} \sim 2 - 2.2$ (see e.g. the review by Done, Gierliński & Kubota 2007). However, this occurs at $\lambda_{Edd} \sim 0.02$ for moderate changes in mass accretion rate (Maccarone 2003), an order of magnitude lower than the spectral differences seen here in the AGN (see also the discussion in Done et al. 2011). This could indicate some subtle differences in the transition due to the very different masses, but in BHB this transition is also associated with the radio jet switching off (Fender, Belloni & Gallo 2004). If the Compton dominated states in AGN correspond to the low/hard state in BHB then we would expect them to be radio loud. However, AGNs are radio-quiet by a factor of 10:1.

This makes unlikely an identification of the two lower λ_{Edd} AGN templates as analogs to the low/hard (or intermediate state) seen in BHB. Instead, there is another state in BHB called the ‘very high’ or ‘steep power law state’, where the disc also peaks at a lower temperature than expected, and where the Comptonised component contains a large fraction of the total luminosity (see e.g. the review by Done, Gierliński & Kubota 2007). However, this state has $\Gamma_{2-10keV} > 2.5$ i.e. the hard X-ray spectra are steep. Yet these AGN have $\Gamma_{2-10keV} < 2$, as well as a soft X-ray excess component. Therefore, to match the AGN with the very high state would require that reflection and/or complex absorption modify the spectrum, producing an apparent soft X-ray excess and a hard power law from an intrinsically steep spectrum. However, the time variability properties of individual objects make it clear that these high mass, relatively low Eddington ratio objects do indeed have two sepa-

Figure 14. The AGN mean SEDs based on different values of the 9 key parameters from Model-B fitting (i.e. including the effect of a colour temperature correction). For each parameter, the 51 sources are sorted according to the parameter value, and then are divided into three equal subsets so that each contains 17 sources. PG 1004+130 is excluded from its subset. Finally, a mean SED is constructed for each of the three subsets after renormalizing each individual SED to the mean luminosity at 2500Å of that subset. The three panels (A, B, C) in each row show the mean SEDs for the subsets classified by the parameter shown in the panel title. In each panel the solid curve is the mean SED, while the shaded coloured region is the $\pm 1\sigma$ deviation. The 2500 Å and 2 keV positions are marked by the vertical solid orange lines, whose relative height indicates the value of α_{ox} . The peak position of the SED is marked by the vertical solid purple line. The average values of some other parameters in that subset are also shown in the panel. Each mean SED has been rescaled by the same arbitrary constant on the Y-axis which is 1×10^{-46} . Note that the energy ranges 1.4 eV < E < 6 eV and 0.3 keV < E < 10 keV, are covered by SDSS, OM and EPIC data respectively, while the SED in the rest energy bands is determined from an extrapolation of the best-fit model.

Figure 14. *continued*

rate components. The intrinsically hard power law which is more variable on short timescales, and a soft X-ray excess which is relatively constant on these timescales but more variable over longer times (e.g. Mkn509: Mehdipour et al. 2011; Noda et al. 2012).

Therefore, the two lowest λ_{Edd} spectra shown in Figure 14 do not look similar to *any* state observed in BHB. Yet these sources span the typical QSO accretion rates (e.g. Steinhardt & Elvis 2010), and indeed our templates are very similar to the mean SED in Elvis et al. (1994). It seems that these most common QSO SED's are not simply analogous to BHB accretion flows. Only the very rare AGN SED's with the highest λ_{Edd} can be well matched to the BHB, as they are similar to the high/soft state (see also Done et al. 2011).

6 DISCUSSION

6.1 Selection Effects

Biases and systematics inherent in this sample have already been discussed at length in Paper-I and Paper-II. The principal imposed selection effect is that sources in our sample are bright nearby AGN ($z < 0.4$). The luminosity of our sources is higher than the average among nearby sources, but only moderate with respect to samples containing higher redshift sources (e.g. Green09; Lusso10). Our sample contains very few sources with $L_{2-10keV} < 5 \times 10^{42}$ erg s⁻¹ or $\lambda_{Edd} < 0.05$. As discussed in Section 3.2.3 and Section 3.6.1, those very low luminosity sources may not follow the linear regression line in the $\kappa_{2-10keV}$ vs. λ_{Edd} plot in Figure 6, and these sources may populate the low $L_{2-10keV}$, low $\kappa_{2-10keV}$ region in Figure 11. It is also possible that these sources may not follow other correlations reported in this paper, thereby weakening the correlations between $L_{2-10keV}$ and M_{BH} and $H\beta$ FWHM. Further studies of large samples are required to test such possibilities.

The weak anti-correlation found between λ_{Edd} and M_{BH} (Table 4) also implies some selection effect. Sources having both low black hole mass and low mass accretion rate are unlikely to be included in our sample as they would be too faint. Hence low mass sources in our sample will have relatively high λ_{Edd} . For higher mass sources, their luminosity will peak when there is a considerable supply of gas around them to be accreted. This occurs around redshift ~ 2 , and as the available gas decreases, the mass accretion rate of high mass AGN in the local universe is suppressed (so-called downsizing, Fanidakis et al. 2010). Therefore, in the local universe high mass sources should have low λ_{Edd} , resulting in the weak anti-correlation found between M_{BH} and λ_{Edd} (Done et al. 2011).

There are also redshift selection effects. Although comparison of parameter correlations with previous work (based on larger samples) results in a general consistency, the question remains whether there could be a redshift dependence in the correlations we find. However, there are some evidences that redshift evolution in the spectral properties of AGN may not be strong (Fan 2006).

6.2 Limitations of the Model and Uncertainties

There is another underlying question, whether the correlations found might arise artificially as a result of our model assumptions. We will consider this point in two ways:

First, there are no direct constraints on the parameters in our SED model. Compared with some previous work (e.g. VF07, Lusso10, Grupe10), our spectral fitting employs the least external constraints on the values of its parameters. The only parameter that is directly constrained is M_{BH} , whose value is restricted by the FWHM of the intermediate and broad components of the $H\beta$ emission line. However, this range often spans more than one order of magnitude, and the best-fit M_{BH} did not exceed the model limits for most sources (see Table C1 of Paper-I). Therefore this constrain should not be strong enough to cause systematics.

Second, for previously known correlations such as λ_{Edd} vs. $\kappa_{2-10keV}$, λ_{Edd} vs. $\Gamma_{2-10keV}$ and $H\beta$ FWHM vs. $\Gamma_{2-10keV}$, our results are all consistent with past studies based on a variety of AGN samples. This suggests that the reported correlations should be intrinsic, and that our results are not strongly contaminated by model assumptions. As discussed in the previous sections, the differences between our results and those previously reported are mainly due to two reasons. One is our exclusion of highly obscured sources, which reduces the non-intrinsic dispersion within these correlations. The other reason is that our parameter values are derived from a detailed spectral fitting, rather than from simply applying scaling relations which will contain high uncertainties.

However, the range of values for each of the 11 key parameters discussed previously could be dominated by model uncertainties, except for $\Gamma_{2-10keV}$, whose measurement is relatively model independent. For this reason we did not adopt the uncertainties returned by *Xspec*, because they must be negligible compared with the model uncertainties. Such model uncertainties are very difficult to estimate, and the values of the same parameter derived from different SED models, can be quite different. As an illustration, in the following paragraphs we will compare the parameter values before and after introducing a colour temperature correction into our broadband SED model.

6.3 The Effect of the Colour Temperature Correction

The colour temperature correction is only important for sources having both a low black hole mass and a high mass accretion rate (see Done et al. 2011 and references therein). So it only affects a small fraction of all the sources in our sample, mainly the NLS1s. The main consequences of introducing a colour temperature correction by using Model-B (i.e. *optxagnf* in *Xspec* v12) are that M_{BH} increases, L_{bol} decreases and so λ_{Edd} decreases. For example, the λ_{Edd} of PG 2233+134 decreases significantly from 14 to 2.4 after using Model-B, making it much less extreme. $\kappa_{2-10keV}$ and $\kappa_{5100\text{\AA}}$ also decrease due to the decrease of L_{bol} . α_{ox} changes slightly but not significantly, because the luminosity at 2500Å is mainly constrained by the OM data (Paper-I). Figure 15 compares the distribution of these parameters between Model-A (Paper-I) and Model-B fitting. Table 6 lists the average values of these parameters for NLS1s, BLS1s

Table 6. The average value of parameters from the best-fit SEDs using Model-A (without a colour temperature correction, Paper-I) and Model-B (with colour temperature correction). The values and their standard deviations are calculated separately for NLS1s, BLS1s and for the whole sample.

Model-	NLS1s A	NLS1s B	BLS1s A	BLS1s B	Whole Sample A	Whole Sample B
$\langle \kappa_{2-10\text{keV}} \rangle$	127^{+197}_{-77}	86^{+96}_{-45}	29^{+44}_{-17}	30^{+38}_{-17}	41^{+85}_{-27}	38^{+58}_{-23}
$\langle \kappa_{5100\text{\AA}} \rangle$	29^{+37}_{-16}	20^{+13}_{-8}	13^{+17}_{-8}	14^{+14}_{-7}	16^{+23}_{-9}	15^{+14}_{-7}
$\langle \lambda_{Edd} \rangle$	$0.95^{+5.33}_{-0.80}$	$0.35^{+0.99}_{-0.26}$	$0.27^{+0.81}_{-0.20}$	$0.25^{+0.52}_{-0.17}$	$0.36^{+1.42}_{-0.29}$	$0.27^{+0.61}_{-0.19}$
$\langle M_{BH} \rangle$	7.11 ± 0.54	7.37 ± 0.47	8.04 ± 0.48	8.10 ± 0.41	7.83 ± 0.64	7.93 ± 0.52
$\langle \alpha_{ox} \rangle$	1.42 ± 0.08	1.39 ± 0.10	1.34 ± 0.16	1.34 ± 0.15	1.36 ± 0.14	1.35 ± 0.14
$\langle L_{bol} \rangle$	45.19 ± 0.54	45.02 ± 0.49	45.59 ± 0.52	45.61 ± 0.53	45.49 ± 0.55	45.47 ± 0.57

and the whole sample, for both Model-A and Model-B fitting. This confirms that the large differences in results from the Model-A and Model-B fittings are mostly restricted to the NLS1s, whose colour temperature corrections are significant.

In order to further investigate the differences between using Model-A and Model-B, we redo all of the above cross-correlation analysis by adopting Model-A parameter values from Paper-I, and then we compare the statistical results in the appendices. Appendix C shows all of the correlation plots that could in principle be modified by the differences between the Model-A and Model-B fittings. In each plot the dashed gray lines are for Model-B fitting (this paper), compared with the solid orange lines for Model-A fitting. It is clear that there are no significant changes in any of these correlation plots. This is further confirmed by the correlation matrix for Model-A fitting in Appendix D. Performing a PCA on this matrix, very similar eigenvectors and eigenvalues are obtained. Appendix E shows the mean SEDs based on the parameter values obtained from Model-A fitting, which does not include the colour temperature correction. Therefore, we conclude that use of the refined Model-B compared with the original Model-A, does not alter the main results reported in this paper, although for individual sources such as the NLS1s, the refined model should be more realistic.

6.4 The Correction for Radiation Pressure

Marconi et al. (2008) suggested that the virial mass estimates should be corrected for the effects of radiation pressure (RP), especially for those sources with high Eddington ratios, such as the NLS1s. In our study the M_{BH} was not derived directly from the virial mass, but was only constrained by the virial masses calculated from the FWHM of the intermediate and broad components of the $H\beta$ line. The final estimate of M_{BH} is derived from the best-fit SED, and so there is no need to correct for the RP effect. However, we may still choose to derive the virial mass from using the FWHM of $H\beta$ profile (narrow component subtracted), and then correct these values for the RP effect. Paper-I has listed and compared these masses (M_{RP}) with the best-fit masses (M_{BF}) from the SED fitting using Model-A. The distributions of these two estimates of masses are very similar, ex-

cept that the average M_{RP} is 0.4 dex higher compared with M_{BF} .

As discussed in previous section, the SED fittings including the colour temperature correction (Model-B) increases the average M_{BF} by 0.27 dex for NLS1s, and 0.05 dex for BLS1s (Table 6). So for the NLS1s using Model-B fitting, the average M_{BF} is just 0.05 dex smaller than the average M_{RP} , while for the BLS1s the difference is still 0.34 dex. Furthermore, no significant difference is found in Table 4 if we substitute M_{RP} for M_{BF} , and cross-correlate with the other 10 SED parameters. The coefficients in Equation 15, 16 only differ by less than 1σ when using M_{RP} instead of M_{BF} . This suggests that the difference between M_{RP} and M_{BF} is far less than the intrinsic dispersion in any of the correlations, and so is not important in our correlation studies.

6.5 The 4000 km s⁻¹ $H\beta$ FWHM Break

The $\text{FWHM}_{H\beta} = 2000 \text{ km s}^{-1}$ is the conventional, but arbitrary value to distinguish between NLS1 and BLS1 (Goodrich 1989). Recently, the limit of 4000 km s^{-1} for the $\text{FWHM}_{H\beta}$ was claimed to be of special interest. For example, when AGNs are divided into two populations based on $\text{FWHM}_{H\beta} = 4000 \text{ km s}^{-1}$ (population A: $\text{FWHM}_{H\beta} \lesssim 4000 \text{ km s}^{-1}$ and B: $\text{FWHM}_{H\beta} \gtrsim 4000 \text{ km s}^{-1}$), it appeared that most radio loud sources are contained in population B (Sulentic et al. 2008). Compared with the RL-RQ and the NLS1-BLS1 divisions, this dividing line in FWHM also seems to be more effective in distinguishing the different SEDs (Sulentic et al. 2008). Furthermore, Zhou10a reported that in the $\text{FWHM}_{H\beta}$ vs. $\Gamma_{2-10\text{keV}}$ correlation plot, there is a change in the slope at $\sim 4000 \text{ km s}^{-1}$, as consistent with our results. They also showed that the the broadest iron $K\alpha$ lines, those with intrinsic width $\sigma > 0.5 \text{ keV}$ have are all found in AGNs with $\text{FWHM}_{H\beta} < 4000 \text{ km s}^{-1}$.

In Section 3.5, we confirmed a slope change at $\text{FWHM}_{H\beta} \simeq 4000 \text{ km s}^{-1}$ in $\text{FWHM}_{H\beta}$ vs. $\Gamma_{2-10\text{keV}}$ correlation plot. All the three RL sources in our sample (purple symbols in Figure 9) have $\text{FWHM}_{H\beta} > 4000 \text{ km s}^{-1}$. To highlight the 27 population A sources in our sample, we use the square symbol to identify these sources in all correlation plots, and we show their distribution in the histograms as the green region. The 12 NLS1s among them are shown as

Figure 15. Comparison of parameter distributions between Model-A and Model-B SED fittings. In each panel the shaded cyan histogram is based on our modified SED fitting using Model-B (listed in Table B2), with the 12 NLS1s highlighted by the shaded orange region. The solid black line shows the parameter histogram for Model-A fitting (listed in Table 3 of Paper-I), with the dashed red line indicating the 12 NLS1s.

the red region. The two-sided KS-Test was used to determine the significance of the difference between the distributions of the sub-samples for the NLS1-BLS1 division, and the population A-B division. Among the 11 key parameters, the population A-B provides a somewhat better division for the 7 parameters: $\kappa_{2-10keV}$, κ_{5100A} , λ_{Edd} , $H\beta$ FWHM, α_{ox} , α_X and α_{UV} ; while NLS1-BLS1 division is better for the other parameters (see Table 7). Therefore, the population A-B division for our RQ Type 1 AGN sample does not seem to be significantly better than the NLS1-BLS1 division.

7 SUMMARY AND FUTURE WORK

7.1 Summary of Principle Results

In this third paper in the series, we have studied the SED properties of our Type 1 AGN sample. We employ a new broadband SED model (*optxagnf* in *Xspec* v12), which includes a colour temperature correction, to construct the SED for each source in the sample. Various parameters were obtained from the results of the SED fitting. A detailed statistical analysis was performed, which can be divided into three major parts:

- In the first part we studied the diverse correlations found among the SED parameters. We divided these parameters into five groups, according to previously reported correlations. Within each group we conducted a detailed cross-correlation analysis, and applied several regression methods. Our results are generally in good agreement with previous

work. However, as a consequence of the unobscured nature of the sample and the more reliable parameter values that resulted from our refined spectral fitting, we were able to reduce the non-intrinsic dispersion and so obtain the intrinsic and better constrained correlations.

For example, we confirmed the linear correlation in $\text{Log}(L_{2500})$ vs. $\text{Log}(L_{2keV})$ with slope ~ 1 . The correlation of $\text{Log}(\kappa_{2-10keV})$ vs. α_{ox} can be approximated using a second order polynomial. The correlation between α_{ox} and $\text{Log}(\lambda_{Edd})$ is weak and dominated by dispersion in intrinsic source properties. Some strong correlations have been confirmed e.g. $\text{Log}(\kappa_{2-10keV})$ vs. $\text{Log}(\lambda_{Edd})$, $\text{Log}(\kappa_{5100})$ vs. $\text{Log}(\lambda_{Edd})$, $\text{Log}(\kappa_{5100})$ vs. $\text{Log}(\kappa_{2-10keV})$, $\Gamma_{2-10keV}$ vs. $\text{Log}(\lambda_{Edd})$, $\Gamma_{2-10keV}$ vs. $\text{Log}(\kappa_{5100})$, $\text{Log}(M_{BH})$ vs. $\text{Log}(\text{FWHM}_{H\beta})$ and $\text{Log}(\kappa_{2-10keV})$ vs. $\text{Log}(M_{BH})$. The correlations in both $\Gamma_{2-10keV}$ vs. $\text{Log}(\text{FWHM}_{H\beta})$ and $\Gamma_{2-10keV}$ vs. $\text{Log}(M_{BH})$ change slopes as $\Gamma_{2-10keV}$ decreases to ~ 1.8 . The break region is $\text{FWHM}_{H\beta} \simeq 4000 \text{ km s}^{-1}$ and $\text{Log}(M_{BH}) \simeq 8.0$. $\Gamma_{2-10keV}$ is almost independent of the $\text{FWHM}_{H\beta}$ after the break region, with a mean value of 1.8. By presenting the correlations between α_X , α_{UV} , α_{ox} and $L_{2-10keV}$, we also confirmed that AGNs with bluer optical/UV spectra tend to have steeper X-ray spectra, and their hard X-ray emission is also weaker. Other strong (anti-)correlations were found for α_X and α_{UV} , such as α_X (α_{UV}) vs. $\kappa_{2-10keV}$, α_X (α_{UV}) vs. κ_{5100A} , α_X (α_{UV}) vs. $\text{FWHM}_{H\beta}$ and α_X (α_{UV}) vs. M_{BH} .

- In the second part of our work, we performed a systematic cross-correlation study by producing the correla-

Table 7. The significance level of the difference in the NLS1-BLS1 pair (N1-B1) and Population A-B pair (Pop. A-B) for values of the 11 key parameters. The two-sided Kolmogorov-Smirnov test is applied. A smaller value suggests a greater difference within each sample division pair.

	$\Gamma_{2-10keV}$	κ_{2-10}	κ_{5100A}	λ_{Edd}	FWHM	M_{BH}	α_{ox}	L_{bol}	$L_{2-10keV}$	α_X	α_{UV}

tion matrix of the 11 key parameters: $\Gamma_{2-10keV}$, $\kappa_{2-10keV}$, κ_{5100A} , λ_{Edd} , $FWHM_{H\beta}$, M_{BH} , α_{ox} , L_{bol} , $L_{2-10keV}$, α_X and α_{UV} . The PCA was performed on the correlation matrix to discover the principal eigenvectors that drive the most correlations. We found that the first two eigenvectors (PC1 and PC2) contain $\sim 80\%$ of all correlations in the matrix. PC1 strongly correlates with M_{BH} , while PC2 is dominated by L_{bol} . In addition both PC1 and PC2 well correlate with λ_{Edd} . Thus the two principle eigenvectors are driven by M_{BH} , λ_{Edd} and L_{bol} (or equivalently $\dot{M}$). Our eigenvectors also have similar properties to the two principal eigenvectors derived by Boroson (2002) based on their optical emission line study.

- In the third part we produced various mean SEDs classified by each of the key parameters. The SED shapes are found to exhibit similar changes with most parameters except L_{bol} . This explains the strong correlations found among these key parameters. A more detailed mean SED comparison suggests that the dispersion within each of the three binned SEDs is minimized (and the difference between them is maximized) for composite parameters which depend on both λ_{Edd} and M_{BH} , such as $\kappa_{2-10keV}$, κ_{5100} and $H\beta$ FWHM. This is because the SED change is not determined solely by any one of these key parameters. It should ultimately depend on both λ_{Edd} and M_{BH} .

- To test the robustness of the main results from our correlation study, we looked at the black hole masses corrected for the effect of radiation pressure. We found no significant differences from using our best-fit black hole masses. We also compared the correlation results between Model-A (without a colour temperature correction) and Model-B (including a colour temperature correction) fitting, and found that they were all very similar.

- The population A-B division for AGNs was compared with the NLS1-BLS1 division, but it did not prove to be a better AGN classification method.

7.2 Future Work

Our sample is limited to relatively high λ_{Edd} , with few objects below $\lambda_{Edd} = 0.05$. These (predominantly LINER) objects are the ones expected to be the counterparts of the low/hard state in BHB. Another important extension would be to increase the sample size and include rare higher mass objects with high Eddington ratios. This would allow the SEDs to be co-added for different λ_{Edd} at a given (fixed) black hole mass, thus providing a direct comparison with the BHB states.

The major result of this study is that the SEDs of AGN exhibit a very wide range, most plausibly as a function of mass accretion rate for a given mass black hole. This clearly shows that so-called unified schemes, where AGN have in-

trinsically identical spectra which are modified by orientation dependent obscuration, are an over simplification of the actual situation. In fact, unobscured AGN can have quite different SED shapes depending on λ_{Edd} , and M_{BH} .

Although not widely appreciated, this is broadly expected by analogy of AGN with BHB. The stellar mass black holes clearly show a dramatic change in spectral shape with λ_{Edd} , but unlike AGN, these changes can be tracked in a single object because of the much shorter timescale for variability. However, while the highest λ_{Edd} spectra appear similar to the disc dominated ‘high/soft state’ seen in BHB, the more typical AGN (with an SED similar to the standard quasar SED template in Elvis et al. (1994)), do not appear to have SED properties which match with any spectral state known in BBB.

This might indicate a physical break in the properties of the accretion flow between stellar mass and supermassive black holes. The most obvious change in physical conditions between these two mass regimes is that AGN discs are strong in the UV, and so are capable of powering substantial mass loss via a UV line driven wind. A consequence of mass loss in the wind is that the accretion rate is no longer constant as a function of radius, causing an intrinsic change in the structure of the accretion flow (e.g. Proga, Stone & Kallman 2000). Emission/absorption/scattering processes in the wind can also change the observed properties of the spectrum (Sim et al. 2010). Further work on theoretical disc models including these effects will show whether standard AGN accretion flows are indeed sculpted by a wind.

ACKNOWLEDGEMENTS

We are very grateful to Dirk Grupe for his useful comments and suggestions. C. Jin acknowledges financial support through Durham Doctoral Fellowship. This work is partially based on data from SDSS, whose funding is provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, the Max Planck Society, and the Higher Education Funding Council for England. This work is also partially based on observations obtained with XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA Member States and the USA (NASA).

Table A1. A summary of references about the correlations among the most important AGN SED parameters. The upper right triangle region shows some most recent works about each correlations pair, while the lower left triangle region shows which cross-correlations are studied in this paper. ‘√’ means this cross-correlation pair is studied in this paper, ‘×’ means not studied. The ‘FWHM’ is the FWHM of narrow component subtracted H β profile.

APPENDIX A: SUMMARY OF REFERENCES FOR SED PARAMETER CORRELATIONS

APPENDIX B: PARAMETER VALUES FROM MODEL-B FITTING (*OPTXAGNF*: WITH COLOUR CORRECTION)

Table B1. Broadband SED fitting parameters using Model-B, and the fitting outputs (L_{bol} , f_d , f_c , f_p). ID: object number, the same as Table 1 in Paper-I; $N_{H,gal}$ and $N_{H,int}$: the fixed galactic and free intrinsic neutral hydrogen column densities in 10^{20} cm^{-2} ; Γ_{pow} : the powerlaw component's slope in the SED fitting, (*) denotes the objects whose powerlaw slopes hit the uplimit of 2.2 and were fixed there; Fpl: the fraction of powerlaw component in the total reprocessed disc emission; R_{cor} : corona (truncation) radius in unit of Gravitational radii (r_g) within which all disc emission is reprocessed into the Comptonisation and powerlaw components; T_e : temperature of the Compton up-scattering electron population; Tau: optical depth of the Comptonisation component; $\log(M_{BH})$: the best-fit black hole mass; $\log(\dot{M})$: total mass accretion rate; L_{bol} : bolometric luminosity integrated from 0.001 keV to 100 keV; f_d , f_c , f_p : luminosity fractions of disc emission, soft Comptonisation and hard X-ray Comptonisation components in the bolometric luminosity; χ^2 : the reduced χ^2 of the broadband SED fitting.

Table B2. Key Parameters from Model-B fitting. ID: object number, the same as Table 1 in Paper-I; $\Gamma_{2-10keV}$: the slope of the single powerlaw fitted to 2-10 keV spectrum. $L_{2-10keV}$: 2-10 keV luminosity (in 10^{44} erg s $^{-1}$); $\kappa_{2-10keV}$: the 2-10keV bolometric correction coefficient; $\lambda L_{2500\text{\AA}}$: the monochromatic luminosity at 2500Å (in 10^{43} erg s $^{-1}$); νL_{2keV} : the monochromatic luminosity at 2keV (in 10^{43} erg s $^{-1}$); α_{ox} : the optical X-ray spectral index; λL_{5100} : the monochromatic luminosity at 5100Å (in 10^{44} erg s $^{-1}$); κ_{5100} : the 5100Å bolometric correction coefficient; $FWHM_{H\beta}$: the narrow component subtracted H β FWHM; L_{bol}/L_{Edd} : the Eddington Ratio; α_X : the soft X-ray slope between 0.2-2 keV (corrected for Galactic and intrinsic absorption), assuming $F_\nu \propto \nu^{-\alpha}$; α_{UV} : the optical/UV slope between 1700-6500Å (corrected for Galactic and intrinsic reddening and absorption).

ID	$\Gamma_{2-10keV}$	$L_{2-10keV}$ $\times 10^{44}$	$\kappa_{2-10keV}$	$\lambda L_{2500\text{\AA}}$ $\times 10^{43}$	νL_{2keV} $\times 10^{43}$	α_{ox}	λL_{5100} $\times 10^{44}$	κ_{5100}	$FWHM_{H\beta}$ $km\ s^{-1}$	L_{bol}/L_{Edd}	α_X	α_{UV}

**APPENDIX C: PARAMETER CROSS-CORRELATIONS USING VALUES FROM MODEL-A FITTING
(*OPTXAGN*: WITHOUT COLOR CORRECTION)**

Similar cross-correlation plots as reported in previous sections but use parameter values from Model-A fitting in Paper-I. In each panel, the various point symbols show Model-A data. The solid orange line is the regression result for these Model-A data using the same regression methods as in previous sections. The dashed gray line is our result from previous sections based on Model-B data. All dotted lines are from the other literatures as indicated in previous sections.

Table D1. The cross-correlation matrix of the 9 key parameters based on Model-A data from Jin et al. (2011). ID 1~9 are given to each parameter. ρ_s is the Spearman's rank coefficient. d_s^1 is probability of random distribution in logarithm. α and β are the bisector regression line coefficients assuming $Y=\beta X+\alpha$. The coefficients in the upper right triangle region assumes the vertical parameters to be X. The coefficients in the lower left triangle region assumes the horizontal parameters to be X.

APPENDIX D: PARAMETER CORRELATIONS MATRIX USING VALUES FROM MODEL-A FITTING (OPTXAGN: WITHOUT COLOR CORRECTION)

**APPENDIX E: MEAN AGN SEDS USING MODEL-A FITTING (*OPTXAGN*: WITHOUT COLOR
CORRECTION)**

Figure E1. The AGN mean SEDs based on different values of the 9 key parameters from Model-A fitting in Paper-I (i.e. without effect of color temperature correction). For each parameter, the 51 sources are sorted according to the parameter value, and are then divided into three subsets evenly so that each subset contains 17 sources. PG 1004+130 is excluded from its subset. Finally, a mean SED is constructed for each of the three subsets after renormalizing each individual SED to the mean 2500 Å luminosity of that subset. The three panels (A, B, C) in each row show the mean SEDs of the subsets classified by the parameter shown in the panel title. In each panel, the solid curve is the mean SED, while the color shaded region is the $\pm 1\sigma$ deviation. The 2500 Å and 2 keV positions are marked by the vertical solid orange lines, whose related height shows the value of α_{ox} . The SED peaking position is also marked by the vertical solid purple line. The average values of some other parameters in that subset are also shown in the panel. All the mean SEDs have been rescaled by the same arbitrary constant in the Y-axis which is 1.3×10^{-46} . Note that the energy ranges $1.4 \text{ eV} < E < 6 \text{ eV}$ and $0.3 \text{ keV} < E < 10 \text{ keV}$ are covered by SDSS, OM and EPIC data, while the SED in the rest energy bands is determined by the extrapolating of the best-fit model.
